This book is released under a CC-BY-4.0 license. Anyone is free to share and adapt this work with attribution.

ISBN-13: 978-1719584463

Acknowledgements

Thanks to my lab for inspiring me, my family for being my people, and to the students for always keeping us on our toes.

Helpful comments on this book came from many sources, including Arne Mooers, Brian O'Meara, Mike Whitlock, Matt Pennell, Rosana Zenil-Ferguson, Bob Thacker, Chelsea Specht, Bob Week, Dave Tank, and dozens of others. Thanks to all.

If you like my publishing model try it yourself. The book barons are rich enough, anyway.

Table of contents

- Chapter 1 - A Macroevolutionary Research Program
- Chapter 2 - Fitting Statistical Models to Data
- Chapter 3 - Introduction to Brownian Motion
- Chapter 4 - Fitting Brownian Motion
- Chapter 5 - Multivariate Brownian Motion
- Chapter 6 - Beyond Brownian Motion
- Chapter 7 - Models of discrete character evolution
- Chapter 8 - Fitting models of discrete character evolution
- Chapter 9 - Beyond the Mk model
- Chapter 10 - Introduction to birth-death models
- Chapter 11 - Fitting birth-death models
- Chapter 12 - Beyond birth-death models
- Chapter 13 - Characters and diversification rates
- Chapter 14 - Summary

Chapter 1: A Macroevolutionary Research Program

Section 1.1: Introduction

Evolution is happening all around us. In many cases – lately, due to technological advances in molecular biology – scientists can now describe the evolutionary process in exquisite detail. For example, we know exactly which genes change in frequency from one generation to the next as mice and lizards evolve a white color to match the pale sands of their novel habitats (Rosenblum et al. 2010). We understand the genetics, development, and biomechanics processes that link changes in a Galapagos finches’ diet to the shape of their bill (Abzhanov et al. 2004). And, in some cases, we can watch as one species splits to become two (for example, Rolshausen et al. 2009).

Detailed studies of evolution over short time-scales have been incredibly fruitful and important for our understanding of biology. But evolutionary biologists have always wanted more than this. Evolution strikes a chord in society because it aims to tell us how we, along with all the other living things that we know about, came to be. This story stretches back some 4 billion years in time. It includes all of the drama that one could possibly want – sex, death, great blooms of life and global catastrophes. It has had “winners” and “losers,” groups that wildly diversified, others that expanded then crashed to extinction, as well as species that have hung on in basically the same form for hundreds of millions of years.

There is, perhaps, no more evocative symbol of this grand view of evolution over deep time than the tree of life (Figure 1.1; Rosindell and Harmon 2012). This branching phylogenetic tree connects all living things through a series of splitting events to a single common ancestor. Recent research has dramatically increased our knowledge of the shape and form of this tree. The tree of life is a rich treasure-trove of information, telling us how species are related to one another, which groups are exceptionally diverse or depauperate, and how life has evolved, formed new species, and spread over the globe. Our understanding of the tree of life, still incomplete but advancing every day, promises to transform

our understand of evolution at the grandest scale (Baum and Smith 2012).

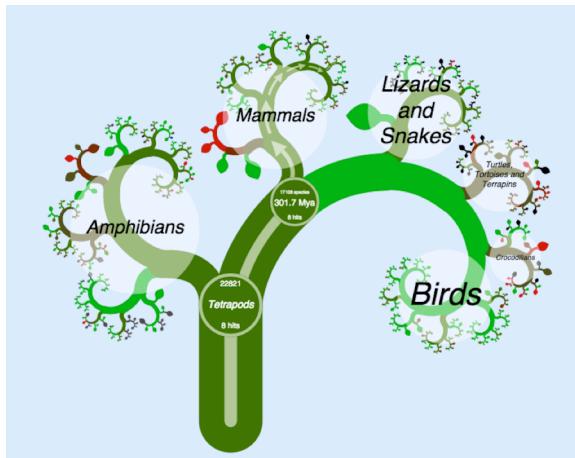

Figure 1.1. A small section of the tree of life showing the relationships among tetrapods, from OneZoom (Rosindell and Harmon 2012). Arrows lead to you. This image can be reused under a CC-BY-4.0 license.

Knowing the evolutionary processes that operate over the course of a few generations, even in great detail, does not automatically give insight into why the tree of life is shaped the way that it is. At the same time, it seems reasonable to hypothesize that the same processes that we can observe now - natural selection, genetic drift, migration, sexual selection, and so on - have been occurring for the last four billion years or so along the branches of the tree. A major challenge for evolutionary biology, then, comes in connecting our knowledge of the mechanisms of evolution with broad-scale patterns seen in the tree of life. This “tree thinking” is what we will explore here.

In this book, I describe methods to connect evolutionary processes to broad-scale patterns in the tree of life. I focus mainly – but not exclusively – on phylogenetic comparative methods. Comparative methods combine biology, mathematics, and computer science to learn about a wide variety of topics in evolution using phylogenetic trees and other associated data (see Harvey and Pagel 1991 for an early review). For example, we can find out which processes must have been common,

and which rare, across clades in the tree of life; whether evolution has proceeded differently in some lineages compared to others; and whether the evolutionary potential that we see playing out in real time is sufficient to explain the diversity of life on earth, or whether we might need additional processes that may come into play only very rarely or over very long timescales, like adaptive radiation or species selection.

This introductory chapter has three sections. First, I lay out the background and context for this book, highlighting the role that I hope it will play for readers. Second, I include some background material on phylogenies - both what they are, and how they are constructed. This is necessary information that leads into the methods presented in the remainder of the chapters of the book; interested readers can also read Felsenstein (Felsenstein 2004), which includes much more detail. Finally, I briefly outline the book's remaining chapters.

Section 1.2: The roots of comparative methods

The comparative approaches in this book stem from and bring together three main fields: population and quantitative genetics, paleontology, and phylogenetics. I will provide a very brief discussion of how these three fields motivate the models and hypotheses in this book (see Pennell and Harmon 2013 for a more comprehensive review).

The fields of population and quantitative genetics include models of how gene frequencies and trait values change through time. These models lie at the core of evolutionary biology, and relate closely to a number of approaches in comparative methods. Population genetics tends to focus on allele frequencies, while quantitative genetics focuses on traits and their heritability; however, genomics has begun to blur this distinction a bit. Both population and quantitative genetics approaches have their roots in the modern synthesis, especially the work of Fisher (1930) and Wright (1984), but both have been greatly elaborated since then (Falconer et al. 1996; see Lynch and Walsh 1998; Rice 2004). Although population and quantitative genetic approaches most commonly focus on change over one or a few generations, they have been applied to macroevolution with great benefit. For example, Lande (1976) provided quantitative genetic predictions for trait

evolution over many generations using Brownian motion and Ornstein-Uhlenbeck models (see Chapter 3). Lynch (1990) later showed that these models predict long-term rates of evolution that are actually too fast; that is, variation among species is too small compared to what we know about the potential of selection and drift (or, even, drift alone!) to change traits. This is, by the way, a great example of the importance of macroevolutionary research from a deep-time perspective. Given the regular observation of strong selection in natural populations, who would have guessed that long-term patterns of divergence are actually less than we would expect, even considering only genetic drift (see also Uyeda et al. 2011)?

Paleontology has, for obvious reasons, focused on macroevolutionary models as an explanation for the distribution of species and traits in the fossil record. Almost all of the key questions that I tackle in this book are also of primary interest to paleontologists - and comparative methods has an especially close relationship to paleobiology, the quantitative mathematical side of paleontology (Valentine 1996; Benton and Harper 2013). For example, a surprising number of the macroevolutionary models and concepts in use today stem from quantitative approaches to paleobiology by Raup and colleagues in the 1970s and 1980s (e.g. Raup et al. 1973; Raup 1985). Many of the models that I will use in this book – for example, birth-death models for the formation and extinction of species – were first applied to macroevolution by paleobiologists.

Finally, comparative methods has deep roots in phylogenetics. In fact, many modern phylogenetic approaches to macroevolution can be traced to Felsenstein's (1985) paper introducing independent contrasts. This paper was unique in three main ways. First, Felsenstein's paper was written in a remarkably clear way, and convinced scientists from a range of disciplines of the necessity and value of placing their comparative work in a phylogenetic context. Second, the method of phylogenetic independent contrasts was computationally fast and straightforward to interpret. And finally, Felsenstein's work suggested a way to connect the previous two topics, quantitative genetics and paleobiology, using math. I discuss independent contrasts, which continue to find new applications, in great detail later in the book. Felsenstein (1985) spawned a whole industry of quantitative approaches that apply

models from population and quantitative genetics, paleobiology, and ecology to data that includes a phylogenetic tree.

25 years ago, “The Comparative Method in Evolutionary Biology,” by Harvey and Pagel (1991) synthesized the new field of comparative methods into a single coherent framework. Even reading this book nearly 25 years later one can still feel the excitement and potential unlocked by a suite of new methods that use phylogenetic trees to understand macroevolution. But in the time since Harvey and Pagel (1991), the field of comparative methods has exploded – especially in the past decade. Much of this progress was, I think, directly inspired by Harvey and Pagel’s book, which went beyond review and advocated a model-based approach for comparative biology. My wildest hope is that my book can serve a similar purpose.

My goals in writing this book, then, are three-fold. First, to provide a general introduction to the mathematical models and statistical approaches that form the core of comparative methods; second, to give just enough detail on statistical machinery to help biologists understand how to tailor comparative methods to their particular questions of interest, and to help biologists get started in developing their own new methods; and finally, to suggest some ideas for how comparative methods might progress over the next few years.

Section 1.3: A brief introduction to phylogenetic trees

It is hard work to reconstruct a phylogenetic tree. This point has been made many times (for example, see Felsenstein 2004), but bears repeating here. There are an enormous number of ways to connect a set of species by a phylogenetic tree – and the number of possible trees grows extremely quickly with the number of species. For example, there are about 5×10^{38} ways to build a phylogenetic tree¹ of 30 species, which is many times larger than the number of stars in the universe. Additionally, the mathematical problem of reconstructing trees in an optimal way from species’ traits is an example of a problem that is “NP-complete,” a class of problems that include some of the most computationally difficult in the world. Building phylogenies is difficult.

The difficulty of building phylogenies is currently reflected in the challenge of reconstructing the tree of life. Some parts of the tree of life are still unresolved even with the tremendous amounts of genomic data that are now available. Accordingly, scientists have devoted a focused effort to solving this difficult problem. There are now a large number of fast and efficient computer programs aimed solely at reconstructing phylogenetic trees (e.g. MrBayes: Ronquist and Huelsenbeck 2003; BEAST: Drummond and Rambaut 2007). Consequently, the number of well-resolved phylogenetic trees available is also increasing rapidly. As we begin to fill in the gaps of the tree of life, we are developing a much clearer idea of the patterns of evolution that have happened over the past 4.5 billion years on Earth.

A core reason that phylogenetic trees are difficult to reconstruct is that they are information-rich². A single tree contains detailed information about the patterns and timing of evolutionary branching events through a group's history. Each branch in a tree tells us about common ancestry of a clade of species, and the start time, end time, and branch length tell us about the timing of speciation events in the past. If we combine a phylogenetic tree with some trait data – for example, mean body size for each species in a genus of mammals – then we can obtain even more information about the evolutionary history of a section of the tree of life.

The most common methods for reconstructing phylogenetic trees use data on species' genes and/or traits. The core information about phylogenetic relatedness of species is carried in shared derived characters; that is, characters that have evolved new states that are shared among all of the species in a clade and not found in the close relatives of that clade. For example, mammals have many shared derived characters, including hair, mammary glands, and specialized inner ear bones.

Phylogenetic trees are often constructed based on genetic (or genomic) data using modern computer algorithms. Several methods can be used to build trees, like parsimony, maximum likelihood, and Bayesian analyses (see Chapter 2). These methods all have distinct assumptions and can give different results. In fact, even within a given statistical framework, different software packages (e.g. Mr. Bayes and BEAST, mentioned above, are both Bayesian approaches) can give different results

for phylogenetic analyses of the same data. The details of phylogenetic tree reconstruction are beyond the scope of this book. Interested readers can read “Inferring Phylogenies” (Felsenstein 2004), “Computational Molecular Evolution” (Yang 2006), or other sources for more information.

For many current comparative methods, we take a phylogenetic tree for a group of species as a given – that is, we assume that the tree is known without error. This assumption is almost never justified. There are many reasons why phylogenetic trees are estimated with error. For example, estimating branch lengths from a few genes is difficult, and the branch lengths that we estimate should be viewed as uncertain. As another example, trees that show the relationships among genes (gene trees) are not always the same as trees that show the relationships among species (species trees). Because of this, the best comparative methods recognize that phylogenetic trees are always estimated with some amount of uncertainty, both in terms of topology and branch lengths, and incorporate that uncertainty into the analysis. I will describe some methods to accomplish this in later chapters.

How do we make sense of the massive amounts of information contained in large phylogenetic trees? The definition of “large” can vary, but we already have trees with tens of thousands of tips, and I think we can anticipate trees with millions of tips in the very near future. These trees are too large to comfortably fit into a human brain. Current tricks for dealing with trees – like banks of computer monitors or long, taped-together printouts – are inefficient and will not work for the huge phylogenetic trees of the future. We need techniques that will allow us to take large phylogenetic trees and extract useful information from them. This information includes, but is not limited to, estimating rates of speciation, extinction, and trait evolution; testing hypotheses about the mode of evolution in a group; identifying adaptive radiations, key innovations, and other macroevolutionary explanations for diversity; and many other things.

Section 1.4: What we can (and can't) learn about evolutionary history from living species

Traditionally, scientists have used fossils to quantify rates and patterns of evolution through long periods of time (sometimes called “macroevolution”). These approaches have been tremendously informative. We now have a detailed picture of the evolutionary dynamics of many groups, from hominids to crocodilians. In some cases, very detailed fossil records of some types of organisms – for example, marine invertebrates – have allowed quantitative tests of particular evolutionary models.

Fossils are particularly good at showing how species diversity and morphological characters change through time. For example, if one has a sequence of fossils with known times of occurrence, one can reconstruct patterns of species diversity through time. A classic example of this is Sepkoski's (1984) reconstruction of the diversity of marine invertebrates over the past 600 million years. One can also quantify the traits of those fossils and measure how they change across various time intervals (e.g. Foote 1997). In some groups, we can make plots of changes in lineage and trait diversity simultaneously (Figure 1.2). Fossils are the only evidence we have for evolutionary lineages that have gone extinct, and they provide valuable direct evidence about evolutionary dynamics in the past.

However, fossil-based approaches face some challenges. The first is that the fossil record is incomplete. This is a well-known phenomenon, identified by Darwin himself (although many new fossils continue to be found). The fossil record is incomplete in some very particular ways that can sometimes hamper our ability to study evolutionary processes using fossils alone. One example is that fossils are rare or absent from some classical examples of adaptive radiation on islands. For example, the entire fossil record of Caribbean anoles, a well-known adaptive radiation of lizards, consists of less than ten specimens preserved in amber (Losos 2009). We similarly lack fossils for other adaptive radiations like African cichlids and Darwin's finches. The absence of fossils in these groups limits our ability to directly study the early stages of adaptive radiation. Another limitation of the fossil record relates to species and

speciation. It is very difficult to identify and classify species in the fossil record – even more difficult than it is to do so for living species. It is hard to tell species apart, and particularly difficult to pin down the exact time when new species split off from their close relatives. In fact, most studies of fossil diversity focus on higher taxonomic groups like genera, families, or orders (see, e.g., Sepkoski 1984). These studies have been immensely valuable but it can be difficult to connect these results to what we know about living species. In fact, it is species (and not genera, families, or orders) that form the basic units of almost all evolutionary studies. So, fossils have great value but also suffer from some particular limitations.

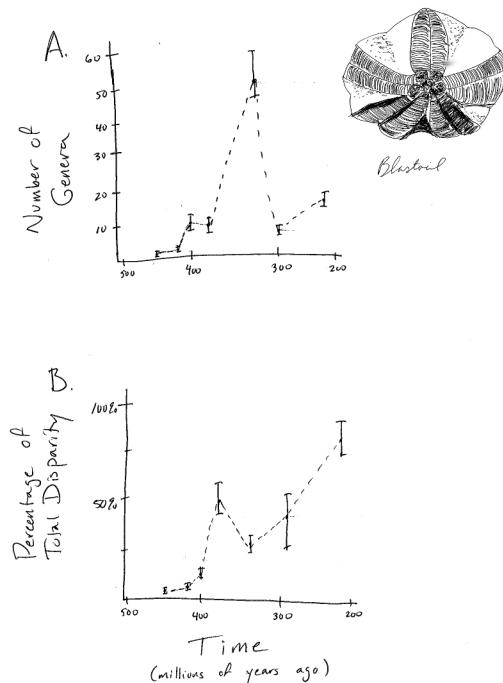

Figure 1.2. Diversity and disparity in the fossil record for the Blastoids. Plots show A. diversity (number of genera) and B. disparity (trait variance) through time. Image by the author, inspired by Foote (1997). This image can be reused under a CC-BY-4.0 license.

Phylogenetic trees represent a rich source of complementary information about the dynamics of species formation through time. Phyloge-

netic approaches provide a useful complement to fossils because their limitations are very different from the limitations of the fossil record. For example, one can often include all of the living species in a group when creating a phylogenetic tree. Additionally, one can use information from detailed systematic and taxonomic studies to identify species, rather than face the ambiguity inherent when using fossils. Phylogenetic trees provide a distinct source of information about evolutionary change that is complementary to approaches based on fossils. However, phylogenetic trees do not provide all of the answers. In particular, there are certain problems that comparative data alone simply cannot address. The most prominent of these, which I will return to later, are reconstructing traits of particular ancestors (ancestral state reconstruction; Losos 2011) and distinguishing between certain types of models where the tempo of evolution changes through time (Slater et al. 2012a). Some authors have argued that extinction, as well, cannot be detected in the shape of a phylogenetic tree (Rabosky 2010). I will argue against this point of view in Chapter 11, but extinction still remains a tricky problem when one is limited to samples from a single time interval (the present day). Phylogenetic trees provide a rich source of information about the past, but we should be mindful of their limitations (Alroy 1999).

Perhaps the best approach would combine fossil and phylogenetic data directly. Paleontologists studying fossils and neontologists studying phylogenetic trees share a common set of mathematical models. This means that, at some point, the two fields can merge, and both types of information can be combined to study evolutionary patterns in a cohesive and integrative way. However, surprisingly little work has so far been done in this area (but see Slater et al. 2012a, Heath et al. (2014)).

Section 1.5: Overview of the book

In this book, I outline statistical procedures for analyzing comparative data. Some methods – such as those for estimating patterns of speciation and extinction through time – require an ultrametric phylogenetic tree. Other approaches model trait evolution, and thus require data

on the traits of species that are included in the phylogenetic tree. The methods also differ as to whether or not they require the phylogenetic tree to be complete – that is, to include every living species descended from a certain ancestor – or can accommodate a smaller sample of the living species.

The book begins with a general discussion of model-fitting approaches to statistics (Chapter 2), with a particular focus on maximum likelihood and Bayesian approaches. In Chapters 3-9, I describe models of character evolution. I discuss approaches to simulating and analyzing the evolution of these characters on a tree. Chapters 10-12 focus on models of diversification, which describe patterns of speciation and extinction through time. I describe methods that allow us to simulate and fit these models to comparative data. Chapter 13 covers combined analyses of both character evolution and lineage diversification. Finally, in Chapter 14 I discuss what we have learned so far about evolution from these approaches, and what we are likely to learn in the future.

There are a number of computer software tools that can be used to carry out the methods described here. In this book, I focus on the statistical software environment R. For each chapter, my course website, in progress, provides sample R code that can be used to carry out all described analyses. I hope that this R code will allow further development of this language for comparative analyses. However, it is possible to carry out the algorithms we describe using other computer software or programming languages (e.g. Arbor, <http://www.arborworkflows.com>).

Statistical comparative methods represent a promising future for evolutionary studies, especially as our knowledge of the tree of life expands. I hope that the methods described in this book can serve as a Rosetta stone that will help us read the tree of life as it is being built.

Footnotes

1: This calculation gives the number of distinct tree shapes (ignoring branch lengths) that are fully bifurcating – that is, each species has two descendants - and rooted.

2: Another difficulty is that the “tree” of life may not look much like a tree due to hybridization, introgression, and other non-branching processes. These issues are currently barely addressed by comparative methods (but see Bastide et al. 2018), and rarely in this book as well! We leave that as a pressing future problem that has only begun to be solved.

Chapter 2: Fitting Statistical Models to Data

Section 2.1: Introduction

Evolution is the product of a thousand stories. Individual organisms are born, reproduce, and die. The net result of these individual life stories over broad spans of time is evolution. At first glance, it might seem impossible to model this process over more than one or two generations. And yet scientific progress relies on creating simple models and confronting them with data. How can we evaluate models that consider evolution over millions of generations?

There is a solution: we can rely on the properties of large numbers to create simple models that represent, in broad brushstrokes, the types of changes that take place over evolutionary time. We can then compare these models to data in ways that will allow us to gain insights into evolution.

This book is about constructing and testing mathematical models of evolution. In my view the best comparative approaches have two features. First, the most useful methods emphasize parameter estimation over test statistics and P-values. Ideal methods fit models that we care about and estimate parameters that have a clear biological interpretation. To be useful, methods must also recognize and quantify uncertainty in our parameter estimates. Second, many useful methods involve model selection, the process of using data to objectively select the best model from a set of possibilities. When we use a model selection approach, we take advantage of the fact that patterns in empirical data sets will reject some models as implausible and support the predictions of others. This sort of approach can be a nice way to connect the results of a statistical analysis to a particular biological question.

In this chapter, I will first give a brief overview of standard hypothesis testing in the context of phylogenetic comparative methods. However, standard hypothesis testing can be limited in complex, real-world situations, such as those encountered commonly in comparative biology. I will then review two other statistical approaches, maximum likelihood

and Bayesian analysis, that are often more useful for comparative methods. This latter discussion will cover both parameter estimation and model selection.

All of the basic statistical approaches presented here will be applied to evolutionary problems in later chapters. It can be hard to understand abstract statistical concepts without examples. So, throughout this part of the chapter, I will refer back to a simple example.

A common simple example in statistics involves flipping coins. To fit with the theme of this book, however, I will change this to flipping a lizard (needless to say, do not try this at home!). Suppose you have a lizard with two sides, “heads” and “tails.” You want to flip the lizard to help make decisions in your life. However, you do not know if this is a fair lizard, where the probability of obtaining heads is 0.5, or not. Perhaps, for example, lizards have a cat-like ability to right themselves when flipped. As an experiment, you flip the lizard 100 times, and obtain heads 63 of those times. Thus, 63 heads out of 100 lizard flips is your data; we will use model comparisons to try to see what these data tell us about models of lizard flipping.

Section 2.2: Standard statistical hypothesis testing

Standard hypothesis testing approaches focus almost entirely on rejecting null hypotheses. In the framework (usually referred to as the frequentist approach to statistics) one first defines a null hypothesis. This null hypothesis represents your expectation if some pattern, such as a difference among groups, is not present, or if some process of interest were not occurring. For example, perhaps you are interested in comparing the mean body size of two species of lizards, an anole and a gecko. Our null hypothesis would be that the two species do not differ in body size. The alternative, which one can conclude by rejecting that null hypothesis, is that one species is larger than the other. Another example might involve investigating two variables, like body size and leg length, across a set of lizard species¹. Here the null hypothesis would be that there is no relationship between body size and leg length. The

alternative hypothesis, which again represents the situation where the phenomenon of interest is actually occurring, is that there is a relationship with body size and leg length. For frequentist approaches, the alternative hypothesis is always the negation of the null hypothesis; as you will see below, other approaches allow one to compare the fit of a set of models without this restriction and choose the best amongst them.

The next step is to define a test statistic, some way of measuring the patterns in the data. In the two examples above, we would consider test statistics that measure the difference in mean body size among our two species of lizards, or the slope of the relationship between body size and leg length, respectively. One can then compare the value of this test statistic in the data to the expectation of this test statistic under the null hypothesis. The relationship between the test statistic and its expectation under the null hypothesis is captured by a P-value. The P-value is the probability of obtaining a test statistic at least as extreme as the actual test statistic in the case where the null hypothesis is true. You can think of the P-value as a measure of how probable it is that you would obtain your data in a universe where the null hypothesis is true. In other words, the P-value measures how probable it is under the null hypothesis that you would obtain a test statistic at least as extreme as what you see in the data. In particular, if the P-value is very large, say $P = 0.94$, then it is extremely likely that your data are compatible with this null hypothesis.

If the test statistic is very different from what one would expect under the null hypothesis, then the P-value will be small. This means that we are unlikely to obtain the test statistic seen in the data if the null hypothesis were true. In that case, we reject the null hypothesis as long as P is less than some value chosen in advance. This value is the significance threshold, α , and is almost always set to $\alpha = 0.05$. By contrast, if that probability is large, then there is nothing “special” about your data, at least from the standpoint of your null hypothesis. The test statistic is within the range expected under the null hypothesis, and we fail to reject that null hypothesis. Note the careful language here – in a standard frequentist framework, you never accept the null hypothesis, you simply fail to reject it.

Getting back to our lizard-flipping example, we can use a frequentist approach. In this case, our particular example has a name; this is a binomial test, which assesses whether a given event with two outcomes has a certain probability of success. In this case, we are interested in testing the null hypothesis that our lizard is a fair flipper; that is, that the probability of heads $p_H = 0.5$. The binomial test uses the number of “successes” (we will use the number of heads, $H = 63$) as a test statistic. We then ask whether this test statistic is either much larger or much smaller than we might expect under our null hypothesis. So, our null hypothesis is that $p_H = 0.5$; our alternative, then, is that p_H takes some other value: $p_H \neq 0.5$.

To carry out the test, we first need to consider how many “successes” we should expect if the null hypothesis were true. We consider the distribution of our test statistic (the number of heads) under our null hypothesis ($p_H = 0.5$). This distribution is a binomial distribution (Figure 2.1).

We can use the known probabilities of the binomial distribution to calculate our P-value. We want to know the probability of obtaining a result at least as extreme as our data when drawing from a binomial distribution with parameters $p = 0.5$ and $n = 100$. We calculate the area of this distribution that lies to the right of 63. This area, $P = 0.003$, can be obtained either from a table, from statistical software, or by using a relatively simple calculation. The value, 0.003, represents the probability of obtaining at least 63 heads out of 100 trials with $p_H = 0.5$. This number is the P-value from our binomial test. Because we only calculated the area of our null distribution in one tail (in this case, the right, where values are greater than or equal to 63), then this is actually a one-tailed test, and we are only considering part of our null hypothesis where $p_H > 0.5$. Such an approach might be suitable in some cases, but more typically we need to multiply this number by 2 to get a two-tailed test; thus, $P = 0.006$. This two-tailed P-value of 0.006 includes the possibility of results as extreme as our test statistic in either direction, either too many or too few heads. Since $P < 0.05$, our chosen α value, we reject the null hypothesis, and conclude that we have an unfair lizard.

In biology, null hypotheses play a critical role in many statistical analy-

Null hypothesis:
 $p_H = 0.5$

Alternative
hypothesis:
 $p_H \neq 0.5$

Test statistic
 $k = 63$

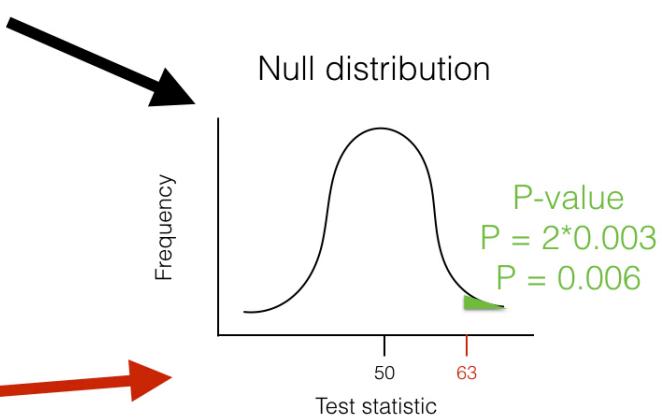

Figure 2.1. The unfair lizard. We use the null hypothesis to generate a null distribution for our test statistic, which in this case is a binomial distribution centered around 50. We then look at our test statistic and calculate the probability of obtaining a result at least as extreme as this value.

ses. So why not end this chapter now? One issue is that biological null hypotheses are almost always uninteresting. They often describe the situation where patterns in the data occur only by chance. However, if you are comparing living species to each other, there are almost always some differences between them. In fact, for biology, null hypotheses are quite often obviously false. For example, two different species living in different habitats are not identical, and if we measure them enough we will discover this fact. From this point of view, both outcomes of a standard hypothesis test are unenlightening. One either rejects a silly hypothesis that was probably known to be false from the start, or one “fails to reject” this null hypothesis². There is much more information to be gained by estimating parameter values and carrying out model selection in a likelihood or Bayesian framework, as we will see below. Still, frequentist statistical approaches are common, have their place in our toolbox, and will come up in several sections of this book.

One key concept in standard hypothesis testing is the idea of statistical error. Statistical errors come in two flavors: type I and type II errors. Type I errors occur when the null hypothesis is true but the investigator mistakenly rejects it. Standard hypothesis testing controls type I errors using a parameter, α , which defines the accepted rate of type I errors. For example, if $\alpha = 0.05$, one should expect to commit a type I error about 5% of the time. When multiple standard hypothesis tests are carried out, investigators often “correct” their P-values using Bonferroni correction. If you do this, then there is only a 5% chance of a single type I error across all of the tests being considered. This singular focus on type I errors, however, has a cost. One can also commit type II errors, when the null hypothesis is false but one fails to reject it. The rate of type II errors in statistical tests can be extremely high. While statisticians do take care to create approaches that have high power, traditional hypothesis testing usually fixes type I errors at 5% while type II error rates remain unknown. There are simple ways to calculate type II error rates (e.g. power analyses) but these are only rarely carried out. Furthermore, Bonferroni correction dramatically increases the type II error rate. This is important because – as stated by Perneger (1998) – “... type II errors are no less false than type I errors.” This extreme emphasis on controlling type I errors at the expense of type II errors is, to me, the main weakness of the frequentist approach³.

I will cover some examples of the frequentist approach in this book, mainly when discussing traditional methods like phylogenetic independent contrasts (PICs). Also, one of the model selection approaches used frequently in this book, likelihood ratio tests, rely on a standard frequentist set-up with null and alternative hypotheses.

However, there are two good reasons to look for better ways to do comparative statistics. First, as stated above, standard methods rely on testing null hypotheses that – for evolutionary questions - are usually very likely, *a priori*, to be false. For a relevant example, consider a study comparing the rate of speciation between two clades of carnivores. The null hypothesis is that the two clades have exactly equal rates of speciation – which is almost certainly false, although we might question how different the two rates might be. Second, standard frequentist methods place too much emphasis on P-values and not enough on the size of statistical effects. A small P-value could reflect either a large effect or very large sample sizes or both.

In summary, frequentist statistical methods are common in comparative statistics but can be limiting. I will discuss these methods often in this book, mainly due to their prevalent use in the field. At the same time, we will look for alternatives whenever possible.

Section 2.3: Maximum likelihood

Section 2.3a: What is a likelihood?

Since all of the approaches described in the remainder of this chapter involve calculating likelihoods, I will first briefly describe this concept. A good general review of likelihood is Edwards (1992). Likelihood is defined as the probability, given a model and a set of parameter values, of obtaining a particular set of data. That is, given a mathematical description of the world, what is the probability that we would see the actual data that we have collected?

To calculate a likelihood, we have to consider a particular model that may have generated the data. That model will almost always have parameter values that need to be specified. We can refer to this speci-

fied model (with particular parameter values) as a hypothesis, H. The likelihood is then:

(eq. 2.1)

$$L(H|D) = Pr(D|H)$$

Here, L and Pr stand for likelihood and probability, D for the data, and H for the hypothesis, which again includes both the model being considered and a set of parameter values. The | symbol stands for “given,” so equation 2.1 can be read as “the likelihood of the hypothesis given the data is equal to the probability of the data given the hypothesis.” In other words, the likelihood represents the probability under a given model and parameter values that we would obtain the data that we actually see.

For any given model, using different parameter values will generally change the likelihood. As you might guess, we favor parameter values that give us the highest probability of obtaining the data that we see. One way to estimate parameters from data, then, is by finding the parameter values that maximize the likelihood; that is, the parameter values that give the highest likelihood, and the highest probability of obtaining the data. These estimates are then referred to as maximum likelihood (ML) estimates. In an ML framework, we suppose that the hypothesis that has the best fit to the data is the one that has the highest probability of having generated that data.

For the example above, we need to calculate the likelihood as the probability of obtaining heads 63 out of 100 lizard flips, given some model of lizard flipping. In general, we can write the likelihood for any combination of H “successes” (flips that give heads) out of n trials. We will also have one parameter, p_H , which will represent the probability of “success,” that is, the probability that any one flip comes up heads. We can calculate the likelihood of our data using the binomial theorem:

(eq. 2.2)

$$L(H|D) = Pr(D|p) = \binom{n}{H} p_H^H (1 - p_H)^{n-H}$$

In the example given, n = 100 and H = 63, so:

(eq. 2.3)

$$L(H|D) = \binom{100}{63} p_H^{63} (1 - p_H)^{37}$$

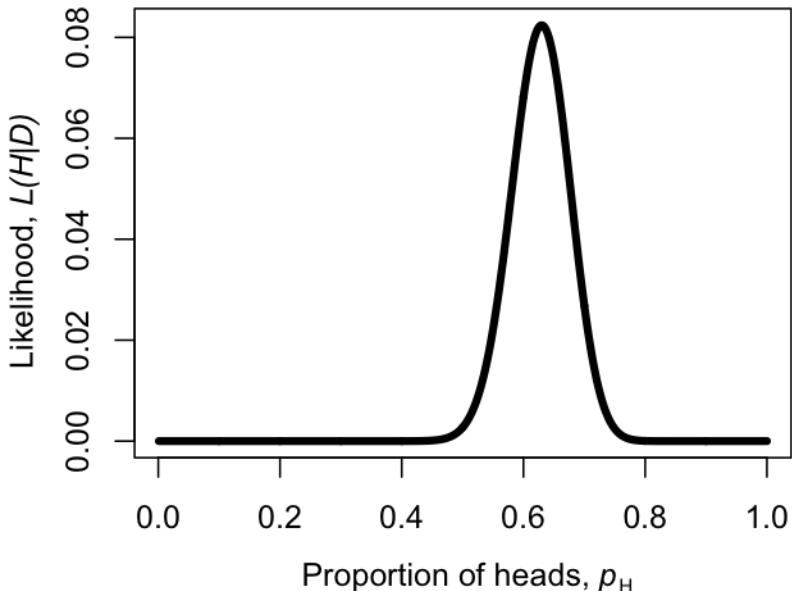

Figure 2.2. Likelihood surface for the parameter p_H , given a coin that has been flipped as heads 63 times out of 100.

We can make a plot of the likelihood, L , as a function of p_H (Figure 2.2). When we do this, we see that the maximum likelihood value of p_H , which we can call \hat{p}_H , is at $\hat{p}_H = 0.63$. This is the “brute force” approach to finding the maximum likelihood: try many different values of the parameters and pick the one with the highest likelihood. We can do this much more efficiently using numerical methods as described in later chapters in this book.

We could also have obtained the maximum likelihood estimate for p_H through differentiation. This problem is much easier if we work with

the ln-likelihood rather than the likelihood itself (note that whatever value of p_H that maximizes the likelihood will also maximize the ln-likelihood, because the log function is strictly increasing). So:

(eq. 2.4)

$$\ln L = \ln \binom{n}{H} + H \ln p_H + (n - H) \ln (1 - p_H)$$

Note that the natural log (ln) transformation changes our equation from a power function to a linear function that is easy to solve. We can differentiate:

(eq. 2.5)

$$\frac{d \ln L}{dp_H} = \frac{H}{p_H} - \frac{(n - H)}{(1 - p_H)}$$

The maximum of the likelihood represents a peak, which we can find by setting the derivative $\frac{d \ln L}{dp_H}$ to zero. We then find the value of p_H that solves that equation, which will be our estimate \hat{p}_H . So we have:

(eq. 2.6)

$$\begin{aligned} \frac{\frac{H}{\hat{p}_H} - \frac{n-H}{1-\hat{p}_H}}{\hat{p}_H} &= 0 \\ \frac{H}{\hat{p}_H} &= \frac{n-H}{1-\hat{p}_H} \\ H(1 - \hat{p}_H) &= \hat{p}_H(n - H) \\ H - H\hat{p}_H &= n\hat{p}_H - H\hat{p}_H \\ H &= n\hat{p}_H \\ \hat{p}_H &= H/n \end{aligned}$$

Notice that, for our simple example, $H/n = 63/100 = 0.63$, which is exactly equal to the maximum likelihood from figure 2.2.

Maximum likelihood estimates have many desirable statistical properties. It is worth noting, however, that they will not always return accurate parameter estimates, even when the data is generated under the actual model we are considering. In fact, ML parameters can sometimes be biased. To understand what this means, we need to formally introduce two new concepts: bias and precision. Imagine that we were to simulate datasets under some model A with parameter a. For each simulation, we then used ML to estimate the parameter \hat{a} for the simulated data. The precision of our ML estimate tells us how different,

on average, each of our estimated parameters \hat{a}_i are from one another. Precise estimates are estimated with less uncertainty. Bias, on the other hand, measures how close our estimates \hat{a}_i are to the true value a . If our ML parameter estimate is biased, then the average of the \hat{a}_i will differ from the true value a . It is not uncommon for ML estimates to be biased in a way that depends on sample size, so that the estimates get closer to the truth as sample size increases, but can be quite far off in a particular direction when the number of data points is small compared to the number of parameters being estimated.

In our example of lizard flipping, we estimated a parameter value of $\hat{p}_H = 0.63$. For the particular case of estimating the parameter of a binomial distribution, our ML estimate is known to be unbiased. And this estimate is different from 0.5 – which was our expectation under the null hypothesis. So is this lizard fair? Or, alternatively, can we reject the null hypothesis that $p_H = 0.5$? To evaluate this, we need to use model selection.

Section 2.3b: The likelihood ratio test

Model selection involves comparing a set of potential models and using some criterion to select the one that provides the “best” explanation of the data. Different approaches define “best” in different ways. I will first discuss the simplest, but also the most limited, of these techniques, the likelihood ratio test. Likelihood ratio tests can only be used in one particular situation: to compare two models where one of the models is a special case of the other. This means that model A is exactly equivalent to the more complex model B with parameters restricted to certain values. We can always identify the simpler model as the model with fewer parameters. For example, perhaps model B has parameters x, y, and z that can take on any values. Model A is the same as model B but with parameter z fixed at 0. That is, A is the special case of B when parameter $z = 0$. This is sometimes described as model A is nested within model B, since every possible version of model A is equal to a certain case of model B, but model B also includes more possibilities.

For likelihood ratio tests, the null hypothesis is always the simpler of

the two models. We compare the data to what we would expect if the simpler (null) model were correct.

For example, consider again our example of flipping a lizard. One model is that the lizard is “fair;” that is, that the probability of heads is equal to $1/2$. A different model might be that the probability of heads is some other value p , which could be $1/2$, $1/3$, or any other value between 0 and 1 . Here, the latter (complex) model has one additional parameter, p_H , compared to the former (simple) model; the simple model is a special case of the complex model when $p_H = 1/2$.

For such nested models, one can calculate the likelihood ratio test statistic as

(eq. 2.7)

$$\Delta = 2 \cdot \ln \frac{L_1}{L_2} = 2 \cdot (\ln L_1 - \ln L_2)$$

Here, Δ is the likelihood ratio test statistic, L_2 the likelihood of the more complex (parameter rich) model, and L_1 the likelihood of the simpler model. Since the models are nested, the likelihood of the complex model will always be greater than or equal to the likelihood of the simple model. This is a direct consequence of the fact that the models are nested. If we find a particular likelihood for the simpler model, we can always find a likelihood equal to that for the complex model by setting the parameters so that the complex model is equivalent to the simple model. So the maximum likelihood for the complex model will either be that value, or some higher value that we can find through searching the parameter space. This means that the test statistic Δ will never be negative. In fact, if you ever obtain a negative likelihood ratio test statistic, something has gone wrong – either your calculations are wrong, or you have not actually found ML solutions, or the models are not actually nested.

To carry out a statistical test comparing the two models, we compare the test statistic Δ to its expectation under the null hypothesis. When sample sizes are large, the null distribution of the likelihood ratio test statistic follows a chi-squared (χ^2) distribution with degrees of freedom equal to the difference in the number of parameters between the two models. This means that if the simpler hypothesis were true, and one

carried out this test many times on large independent datasets, the test statistic would approximately follow this χ^2 distribution. To reject the simpler (null) model, then, one compares the test statistic with a critical value derived from the appropriate χ^2 distribution. If the test statistic is larger than the critical value, one rejects the null hypothesis. Otherwise, we fail to reject the null hypothesis. In this case, we only need to consider one tail of the χ^2 test, as every deviation from the null model will push us towards higher Δ values and towards the right tail of the distribution.

For the lizard flip example above, we can calculate the ln-likelihood under a hypothesis of $p_H = 0.5$ as:

(eq. 2.8)

$$\begin{aligned}\ln L_1 &= \ln\left(\frac{100}{63}\right) + 63 \cdot \ln 0.5 + (100 - 63) \cdot \ln(1 - 0.5) \\ \ln L_1 &= -5.92\end{aligned}$$

We can compare this to the likelihood of our maximum-likelihood estimate :

(eq. 2.9)

$$\begin{aligned}\ln L_2 &= \ln\left(\frac{100}{63}\right) + 63 \cdot \ln 0.63 + (100 - 63) \cdot \ln(1 - 0.63) \\ \ln L_2 &= -2.50\end{aligned}$$

We then calculate the likelihood ratio test statistic:

(eq. 2.10)

$$\begin{aligned}\Delta &= 2 \cdot (\ln L_2 - \ln L_1) \\ \Delta &= 2 \cdot (-2.50 - -5.92) \\ \Delta &= 6.84\end{aligned}$$

If we compare this to a χ^2 distribution with one d.f., we find that $P = 0.009$. Because this P-value is less than the threshold of 0.05, we reject the null hypothesis, and support the alternative. We conclude that this is not a fair lizard. As you might expect, this result is consistent with

our answer from the binomial test in the previous section. However, the approaches are mathematically different, so the two P-values are not identical.

Although described above in terms of two competing hypotheses, likelihood ratio tests can be applied to more complex situations with more than two competing models. For example, if all of the models form a sequence of increasing complexity, with each model a special case of the next more complex model, one can compare each pair of hypotheses in sequence, stopping the first time the test statistic is non-significant. Alternatively, in some cases, hypotheses can be placed in a bifurcating choice tree, and one can proceed from simple to complex models down a particular path of paired comparisons of nested models. This approach is commonly used to select models of DNA sequence evolution (Posada and Crandall 1998).

Section 2.3c: The Akaike information criterion (AIC)

You might have noticed that the likelihood ratio test described above has some limitations. Especially for models involving more than one parameter, approaches based on likelihood ratio tests can only do so much. For example, one can compare a series of models, some of which are nested within others, using an ordered series of likelihood ratio tests. However, results will often depend strongly on the order in which tests are carried out. Furthermore, often we want to compare models that are not nested, as required by likelihood ratio tests. For these reasons, another approach, based on the Akaike Information Criterion (AIC), can be useful.

The AIC value for a particular model is a simple function of the likelihood L and the number of parameters k :

(eq. 2.11)

$$AIC = 2k - 2\ln L$$

This function balances the likelihood of the model and the number of parameters estimated in the process of fitting the model to the data. One can think of the AIC criterion as identifying the model that provides the most efficient way to describe patterns in the data

with few parameters. However, this shorthand description of AIC does not capture the actual mathematical and philosophical justification for equation (2.11). In fact, this equation is not arbitrary; instead, its exact trade-off between parameter numbers and log-likelihood difference comes from information theory (for more information, see Burnham and Anderson 2003, Akaike (1998)).

The AIC equation (2.11) above is only valid for quite large sample sizes relative to the number of parameters being estimated (for n samples and k parameters, $n/k > 40$). Most empirical data sets include fewer than 40 independent data points per parameter, so a small sample size correction should be employed:

(eq. 2.12)

$$AIC_C = AIC + \frac{2k(k+1)}{n-k-1}$$

This correction penalizes models that have small sample sizes relative to the number of parameters; that is, models where there are nearly as many parameters as data points. As noted by Burnham and Anderson (2003), this correction has little effect if sample sizes are large, and so provides a robust way to correct for possible bias in data sets of any size. I recommend always using the small sample size correction when calculating AIC values.

To select among models, one can then compare their AIC_c scores, and choose the model with the smallest value. It is easier to make comparisons in AIC_c scores between models by calculating the difference, ΔAIC_c . For example, if you are comparing a set of models, you can calculate ΔAIC_c for model i as:

(eq. 2.13)

$$\Delta AIC_{c_i} = AIC_{c_i} - AIC_{c_{min}}$$

where AIC_{c_i} is the AIC_c score for model i and $AIC_{c_{min}}$ is the minimum AIC_c score across all of the models.

As a broad rule of thumb for comparing AIC values, any model with a ΔAIC_{c_i} of less than four is roughly equivalent to the model with the lowest AIC_c value. Models with ΔAIC_{c_i} between 4 and 8 have little

support in the data, while any model with a ΔAIC_{c_i} greater than 10 can safely be ignored.

Additionally, one can calculate the relative support for each model using Akaike weights. The weight for model i compared to a set of competing models is calculated as:

(eq. 2.14)

$$w_i = \frac{e^{-\Delta AIC_{c_i}/2}}{\sum_i e^{-\Delta AIC_{c_i}/2}}$$

The weights for all models under consideration sum to 1, so the w_i for each model can be viewed as an estimate of the level of support for that model in the data compared to the other models being considered.

Returning to our example of lizard flipping, we can calculate AIC_c scores for our two models as follows:

(eq. 2.15)

$$\begin{aligned} AIC_1 &= 2k_1 - 2\ln L_1 = 2 \cdot 0 - 2 \cdot -5.92 \\ AIC_1 &= 11.8 \\ AIC_2 &= 2k_2 - 2\ln L_2 = 2 \cdot 1 - 2 \cdot -2.50 \\ AIC_2 &= 7.0 \end{aligned}$$

Our example is a bit unusual in that model one has no estimated parameters; this happens sometimes but is not typical for biological applications. We can correct these values for our sample size, which in this case is $n = 100$ lizard flips:

(eq. 2.16)

$$\begin{aligned} AIC_{c_1} &= AIC_1 + \frac{2k_1(k_1+1)}{n-k_1-1} \\ AIC_{c_1} &= 11.8 + \frac{2 \cdot 0(0+1)}{100-0-1} \\ AIC_{c_1} &= 11.8 \\ AIC_{c_2} &= AIC_2 + \frac{2k_2(k_2+1)}{n-k_2-1} \\ AIC_{c_2} &= 7.0 + \frac{2 \cdot 1(1+1)}{100-1-1} \\ AIC_{c_2} &= 7.0 \end{aligned}$$

Notice that, in this particular case, the correction did not affect our AIC values, at least to one decimal place. This is because the sample size is large relative to the number of parameters. Note that model 2 has the smallest AIC_c score and is thus the model that is best supported by the data. Noting this, we can now convert these AIC_c scores to a relative scale:

(eq. 2.17)

$$\begin{aligned}\Delta AIC_{c_1} &= AIC_{c_1} - AIC_{c\min} \\ &= 11.8 - 7.0 \\ &= 4.8\end{aligned}$$

Note that the ΔAIC_{c_i} for model 1 is greater than four, suggesting that this model (the “fair” lizard) has little support in the data. This is again consistent with all of the results that we’ve obtained so far using both the binomial test and the likelihood ratio test. Finally, we can use the relative AICc scores to calculate Akaike weights:

(eq. 2.18)

$$\begin{aligned}\sum_i e^{-\Delta_i/2} &= e^{-\Delta_1/2} + e^{-\Delta_2/2} \\ &= e^{-4.8/2} + e^{-0/2} \\ &= 1.09\end{aligned}$$

Our results are again consistent with the results of the likelihood ratio test. The relative likelihood of an unfair lizard is 0.92, and we can be quite confident that our lizard is not a fair flipper.

AIC weights are also useful for another purpose: we can use them to get model-averaged parameter estimates. These are parameter estimates that are combined across different models proportional to the support for those models. As a thought example, imagine that we are considering two models, A and B, for a particular dataset. Both model A and model B have the same parameter p , and this is the parameter we are particularly interested in. In other words, we do not know which model is the best model for our data, but what we really need is a good estimate of p . We can do that using model averaging. If model A has

a high AIC weight, then the model-averaged parameter estimate for p will be very close to our estimate of p under model A; however, if both models have about equal support then the parameter estimate will be close to the average of the two different estimates. Model averaging can be very useful in cases where there is a lot of uncertainty in model choice for models that share parameters of interest. Sometimes the models themselves are not of interest, but need to be considered as possibilities; in this case, model averaging lets us estimate parameters in a way that is not as strongly dependent on our choice of models.

Section 2.4: Bayesian statistics

Section 2.4a: Bayes Theorem

Recent years have seen tremendous growth of Bayesian approaches in reconstructing phylogenetic trees and estimating their branch lengths. Although there are currently only a few Bayesian comparative methods, their number will certainly grow as comparative biologists try to solve more complex problems. In a Bayesian framework, the quantity of interest is the posterior probability, calculated using Bayes' theorem:

(eq. 2.19)

$$Pr(H|D) = \frac{Pr(D|H) \cdot Pr(H)}{Pr(D)}$$

The benefit of Bayesian approaches is that they allow us to estimate the probability that the hypothesis is true given the observed data, $Pr(H|D)$. This is really the sort of probability that most people have in mind when they are thinking about the goals of their study. However, Bayes theorem also reveals a cost of this approach. Along with the likelihood, $Pr(D|H)$, one must also incorporate prior knowledge about the probability that any given hypothesis is true - $Pr(H)$. This represents the prior belief that a hypothesis is true, even before consideration of the data at hand. This prior probability must be explicitly quantified in all Bayesian statistical analyses. In practice, scientists often seek to use “uninformative” priors that have little influence on the posterior distribution - although even the term “uninformative” can be

confusing, because the prior is an integral part of a Bayesian analysis. The term $Pr(D)$ is also an important part of Bayes theorem, and can be calculated as the probability of obtaining the data integrated over the prior distributions of the parameters:

(eq. 2.20)

$$Pr(D) = \int_H Pr(H|D)Pr(H)dH$$

However, $Pr(D)$ is constant when comparing the fit of different models for a given data set and thus has no influence on Bayesian model selection under most circumstances (and all the examples in this book).

In our example of lizard flipping, we can do an analysis in a Bayesian framework. For model 1, there are no free parameters. Because of this, $Pr(H) = 1$ and $Pr(D|H) = P(D)$, so that $Pr(H|D) = 1$. This may seem strange but what the result means is that our data has no influence on the structure of the model. We do not learn anything about a model with no free parameters by collecting data!

If we consider model 2 above, the parameter p_H must be estimated. We can set a uniform prior between 0 and 1 for p_H , so that $f(p_H) = 1$ for all p_H in the interval $[0,1]$. We can also write this as “our prior for p_h is $U(0,1)$ ”. Then:

(eq. 2.21)

$$Pr(H|D) = \frac{Pr(D|H) \cdot Pr(H)}{Pr(D)} = \frac{P(H|p_H, N)f(p_H)}{\int_0^1 P(H|p_H, N)f(p_h)dp_H}$$

Next we note that $Pr(D|H)$ is the likelihood of our data given the model, which is already stated above as equation 2.2. Plugging this into our equation, we have:

(eq. 2.22)

$$Pr(H|D) = \frac{\binom{N}{H} p_H^H (1 - p_H)^{N-H}}{\int_0^1 \binom{N}{H} p_H^H (1 - p_H)^{N-H} dp_H}$$

This ugly equation actually simplifies to a beta distribution wiki, which can be expressed more simply as:

(eq. 2.23)

$$Pr(H|D) = \frac{(N+1)!}{H!(N-H)!} p_H^H (1-p_H)^{N-H}$$

We can compare this posterior distribution of our parameter estimate, p_H , given the data, to our uniform prior (Figure 2.3). If you inspect this plot, you see that the posterior distribution is very different from the prior – that is, the data have changed our view of the values that parameters should take. Again, this result is qualitatively consistent with both the frequentist and ML approaches described above. In this case, we can see from the posterior distribution that we can be quite confident that our parameter p_H is not 0.5.

As you can see from this example, Bayes theorem lets us combine our prior belief about parameter values with the information from the data in order to obtain a posterior. These posterior distributions are very easy to interpret, as they express the probability of the model parameters given our data. However, that clarity comes at a cost of requiring an explicit prior. Later in the book we will learn how to use this feature of Bayesian statistics to our advantage when we actually do have some prior knowledge about parameter values.

Section 2.4b: Bayesian MCMC

The other main tool in the toolbox of Bayesian comparative methods is the use of Markov-chain Monte Carlo (MCMC) tools to calculate posterior probabilities. MCMC techniques use an algorithm that uses a “chain” of calculations to sample the posterior distribution. MCMC requires calculation of likelihoods but not complicated mathematics (e.g. integration of probability distributions, as in equation 2.22), and so represents a more flexible approach to Bayesian computation. Frequently, the integrals in equation 2.21 are intractable, so that the most efficient way to fit Bayesian models is by using MCMC. Also, setting up an MCMC is, in my experience, easier than people expect!

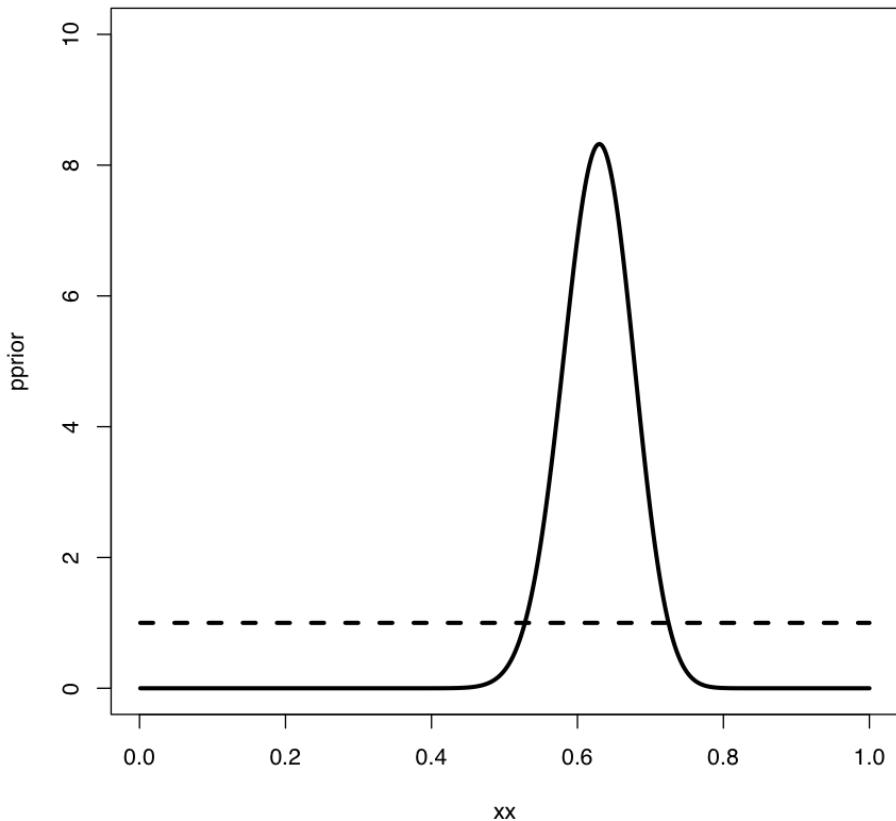

Figure 2.3. Bayesian prior (dotted line) and posterior (solid line) distributions for lizard flipping.

An MCMC analysis requires that one constructs and samples from a Markov chain. A Markov chain is a random process that changes from one state to another with certain probabilities that depend only on the current state of the system, and not what has come before. A simple example of a Markov chain is the movement of a playing piece in the game Chutes and Ladders; the position of the piece moves from one square to another following probabilities given by the dice and the layout of the game board. The movement of the piece from any square on the board does not depend on how the piece got to that square.

Some Markov chains have an equilibrium distribution, which is a stable probability distribution of the model's states after the chain has run for a very long time. For Bayesian analysis, we use a technique called a Metropolis-Hastings algorithm to construct a special Markov chain that has an equilibrium distribution that is the same as the Bayesian posterior distribution of our statistical model. Then, using a random simulation on this chain (this is the Markov-chain Monte Carlo, MCMC), we can sample from the posterior distribution of our model.

In simpler terms: we use a set of well-defined rules. These rules let us walk around parameter space, at each step deciding whether to accept or reject the next proposed move. Because of some mathematical proofs that are beyond the scope of this chapter, these rules guarantee that we will eventually be accepting samples from the Bayesian posterior distribution - which is what we seek.

The following algorithm uses a Metropolis-Hastings algorithm to carry out a Bayesian MCMC analysis with one free parameter:

1. Get a starting parameter value.
 - Sample a starting parameter value, p_0 , from the prior distribution.
2. Starting with $i = 1$, propose a new parameter for generation i .
 - Given the current parameter value, p , select a new proposed parameter value, p' , using the proposal density $Q(p'|p)$.
3. Calculate three ratios.
 - a. The prior odds ratio. This is the ratio of the probability of drawing the parameter values p and p' from the prior (eq.

2.24).

$$R_{prior} = \frac{P(p')}{P(p)}$$

- b. The proposal density ratio. This is the ratio of probability of proposals going from p to p' and the reverse. Often, we purposefully construct a proposal density that is symmetrical. When we do that, $Q(p'|p) = Q(p|p')$ and $a_2 = 1$, simplifying the calculations (eq. 2.25).

$$R_{proposal} = \frac{Q(p'|p)}{Q(p|p')}$$

- c. The likelihood ratio. This is the ratio of probabilities of the data given the two different parameter values (eq. 2.26).

$$R_{likelihood} = \frac{L(p'|D)}{L(p|D)} = \frac{P(D|p')}{P(D|p)}$$

4. Multiply. Find the product of the prior odds, proposal density ratio, and the likelihood ratio (eq. 2.27).

$$R_{accept} = R_{prior} \cdot R_{proposal} \cdot R_{likelihood}$$

5. Accept or reject. Draw a random number x from a uniform distribution between 0 and 1. If $x < R_{accept}$, accept the proposed value of p' ($p_i = p'$); otherwise reject, and retain the current value p ($p_i = p$).
 6. Repeat. Repeat steps 2-5 a large number of times.
-

Carrying out these steps, one obtains a set of parameter values, p_i , where i is from 1 to the total number of generations in the MCMC. Typically, the chain has a “burn-in” period at the beginning. This is the time before the chain has reached a stationary distribution, and can be observed when parameter values show trends through time and the

likelihood for models has yet to plateau. If you eliminate this “burn-in” period, then, as discussed above, each step in the chain is a sample from the posterior distribution. We can summarize the posterior distributions of the model parameters in a variety of ways; for example, by calculating means, 95% confidence intervals, or histograms.

We can apply this algorithm to our coin-flipping example. We will consider the same prior distribution, $U(0, 1)$, for the parameter p . We will also define a proposal density, $Q(p'|p) U(p - \epsilon, p + \epsilon)$. That is, we will add or subtract a small number ($\epsilon \leq 0.01$) to generate proposed values of p' given p .

To start the algorithm, we draw a value of p from the prior. Let’s say for illustrative purposes that the value we draw is 0.60. This becomes our current parameter estimate. For step two, we propose a new value, p' , by drawing from our proposal distribution. We can use $\epsilon = 0.01$ so the proposal distribution becomes $U(0.59, 0.61)$. Let’s suppose that our new proposed value $p' = 0.595$.

We then calculate our three ratios. Here things are simpler than you might have expected for two reasons. First, recall that our prior probability distribution is $U(0, 1)$. The density of this distribution is a constant (1.0) for all values of p and p' . Because of this, the prior odds ratio for this example is always:

(eq. 2.28)

$$R_{prior} = \frac{P(p')}{P(p)} = \frac{1}{1} = 1$$

Similarly, because our proposal distribution is symmetrical, $Q(p'|p) = Q(p|p')$ and $R_{proposal} = 1$. That means that we only need to calculate the likelihood ratio, $R_{likelihood}$ for p and p' . We can do this by plugging our values for p (or p') into equation 2.2:

(eq. 2.29)

$$P(D|p) = \binom{N}{H} p^H (1-p)^{N-H} = \binom{100}{63} 0.6^6 3 (1-0.6)^{100-63} = 0.068$$

Likewise, (eq. 2.30)

$$P(D|p') = \binom{N}{H} p'^H (1-p')^{N-H} = \binom{100}{63} 0.595^6 3(1-0.595)^{100-63} = 0.064$$

The likelihood ratio is then:

(eq. 2.31)

$$R_{likelihood} = \frac{P(D|p')}{P(D|p)} = \frac{0.064}{0.068} = 0.94$$

We can now calculate $R_{accept} = R_{prior} \cdot R_{proposal} \cdot R_{likelihood} = 1 \cdot 1 \cdot 0.94 = 0.94$. We next choose a random number between 0 and 1 – say that we draw $x = 0.34$. We then notice that our random number x is less than or equal to R_{accept} , so we accept the proposed value of p' . If the random number that we drew were greater than 0.94, we would reject the proposed value, and keep our original parameter value $p = 0.60$ going into the next generation.

If we repeat this procedure a large number of times, we will obtain a long chain of values of p . You can see the results of such a run in Figure 2.4. In panel A, I have plotted the likelihoods for each successive value of p . You can see that the likelihoods increase for the first ~ 1000 or so generations, then reach a plateau around $\ln L = -3$. Panel B shows a plot of the values of p , which rapidly converge to a stable distribution around $p = 0.63$. We can also plot a histogram of these posterior estimates of p . In panel C, I have done that – but with a twist. Because the MCMC algorithm creates a series of parameter estimates, these numbers show autocorrelation – that is, each estimate is similar to estimates that come just before and just after. This autocorrelation can cause problems for data analysis. The simplest solution is to subsample these values, picking only, say, one value every 100 generations. That is what I have done in the histogram in panel C. This panel also includes the analytic posterior distribution that we calculated above – notice how well our Metropolis-Hastings algorithm did in reconstructing this distribution! For comparative methods in general, analytic posterior distributions are difficult or impossible to construct, so approximation using MCMC is very common.

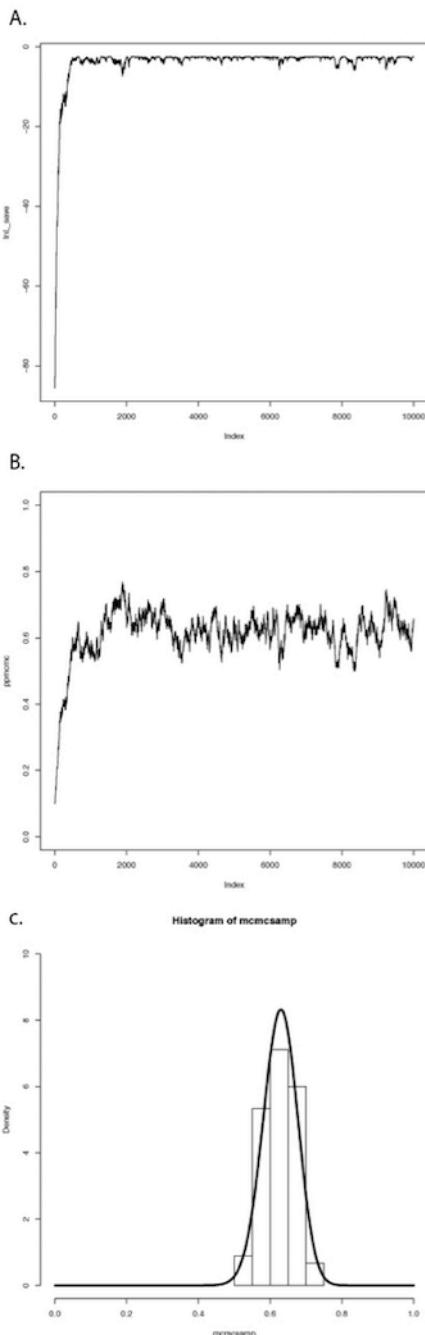

Figure 2.4. Bayesian MCMC from lizard flipping example.

This simple example glosses over some of the details of MCMC algorithms, but we will get into those details later, and there are many other books that treat this topic in great depth (e.g. Christensen et al. 2010). The point is that we can solve some of the challenges involved in Bayesian statistics using numerical “tricks” like MCMC, that exploit the power of modern computers to fit models and estimate model parameters.

Section 2.4c: Bayes factors

Now that we know how to use data and a prior to calculate a posterior distribution, we can move to the topic of Bayesian model selection. We already learned one general method for model selection using AIC. We can also do model selection in a Bayesian framework. The simplest way is to calculate and then compare the posterior probabilities for a set of models under consideration. One can do this by calculating Bayes factors:

(eq. 2.32)

$$B_{12} = \frac{Pr(D|H_1)}{Pr(D|H_2)}$$

Bayes factors are ratios of the marginal likelihoods $P(D|H)$ of two competing models. They represent the probability of the data averaged over the posterior distribution of parameter estimates. It is important to note that these marginal likelihoods are different from the likelihoods used above for *AIC* model comparison in an important way. With *AIC* and other related tests, we calculate the likelihoods for a given model and a particular set of parameter values – in the coin flipping example, the likelihood for model 2 when $p_H = 0.63$. By contrast, Bayes factors’ marginal likelihoods give the probability of the data averaged over all possible parameter values for a model, weighted by their prior probability.

Because of the use of marginal likelihoods, Bayes factor allows us to do model selection in a way that accounts for uncertainty in our parameter estimates – again, though, at the cost of requiring explicit prior probabilities for all model parameters. Such comparisons can

be quite different from likelihood ratio tests or comparisons of AIC_c scores. Bayes factors represent model comparisons that integrate over all possible parameter values rather than comparing the fit of models only at the parameter values that best fit the data. In other words, AIC_c scores compare the fit of two models given particular estimated values for all of the parameters in each of the models. By contrast, Bayes factors make a comparison between two models that accounts for uncertainty in their parameter estimates. This will make the biggest difference when some parameters of one or both models have relatively wide uncertainty. If all parameters can be estimated with precision, results from both approaches should be similar.

Calculation of Bayes factors can be quite complicated, requiring integration across probability distributions. In the case of our coin-flipping problem, we have already done that to obtain the beta distribution in equation 2.22. We can then calculate Bayes factors to compare the fit of two competing models. Let's compare the two models for coin flipping considered above: model 1, where $p_H = 0.5$, and model 2, where $p_H = 0.63$. Then:

(eq. 2.33)

$$\begin{aligned}
 Pr(D|H_1) &= \binom{100}{63} 0.5^{0.63} (1 - 0.5)^{100-63} \\
 &= 0.00270 \\
 Pr(D|H_2) &= \int_{p=0}^1 \binom{100}{63} p^{63} (1 - p)^{100-63} \\
 &= \binom{100}{63} \beta(38, 64) \\
 &= 0.0099 \\
 B_{12} &= \frac{0.0099}{0.00270} \\
 &= 3.67
 \end{aligned}$$

In the above example, $\beta(x, y)$ is the Beta function. Our calculations show that the Bayes factor is 3.67 in favor of model 2 compared to model 1. This is typically interpreted as substantial (but not decisive) evidence in favor of model 2. Again, we can be reasonably confident that our lizard is not a fair flipper.

In the lizard flipping example we can calculate Bayes factors exactly because we know the solution to the integral in equation 2.33. How-

ever, if we don't know how to solve this equation (a typical situation in comparative methods), we can still approximate Bayes factors from our MCMC runs. Methods to do this, including arrogance sampling and stepping stone models (Xie et al. 2011; Perrakis et al. 2014), are complex and beyond the scope of this book. However, one common method for approximating Bayes Factors involves calculating the harmonic mean of the likelihoods over the MCMC chain for each model. The ratio of these two likelihoods is then used as an approximation of the Bayes factor (Newton and Raftery 1994). Unfortunately, this method is extremely unreliable, and probably should never be used (see Neal 2008 for more details).

Section 2.5: AIC versus Bayes

Before I conclude this section, I want to highlight another difference in the way that *AIC* and Bayes approaches deal with model complexity. This relates to a subtle philosophical distinction that is controversial among statisticians themselves so I will only sketch out the main point; see a real statistics book like Burnham and Anderson (2003) or Gelman et al. (2013) for further details. When you compare Bayes factors, you assume that one of the models you are considering is actually the true model that generated your data, and calculate posterior probabilities based on that assumption. By contrast, *AIC* assumes that reality is more complex than any of your models, and you are trying to identify the model that most efficiently captures the information in your data. That is, even though both techniques are carrying out model selection, the basic philosophy of how these models are being considered is very different: choosing the best of several simplified models of reality, or choosing the correct model from a set of alternatives.

The debate between Bayesian and likelihood-based approaches often centers around the use of priors in Bayesian statistics, but the distinction between models and "reality" is also important. More specifically, it is hard to imagine a case in comparative biology where one would be justified in the Bayesian assumption that one has identified the true model that generated the data. This also explains why *AIC*-based approaches typically select more complex models than Bayesian

approaches. In an *AIC* framework, one assumes that reality is very complex and that models are approximations; the goal is to figure out how much added model complexity is required to efficiently explain the data. In cases where the data are actually generated under a very simple model, *AIC* may err in favor of overly complex models. By contrast, Bayesian analyses assume that one of the models being considered is correct. This type of analysis will typically behave appropriately when the data are generated under a simple model, but may be unpredictable when data are generated by processes that are not considered by any of the models. However, Bayesian methods account for uncertainty much better than AIC methods, and uncertainty is a fundamental aspect of phylogenetic comparative methods.

In summary, Bayesian approaches are useful tools for comparative biology, especially when combined with MCMC computational techniques. They require specification of a prior distribution and assume that the “true” model is among those being considered, both of which can be drawbacks in some situations. A Bayesian framework also allows us to much more easily account for phylogenetic uncertainty in comparative analysis. Many comparative biologists are pragmatic, and use whatever methods are available to analyze their data. This is a reasonable approach but one should remember the assumptions that underlie any statistical result.

Section 2.6: Models and comparative methods

For the rest of this book I will introduce several models that can be applied to evolutionary data. I will discuss how to simulate evolutionary processes under these models, how to compare data to these models, and how to use model selection to discriminate amongst them. In each section, I will describe standard statistical tests (when available) along with ML and Bayesian approaches.

One theme in the book is that I emphasize fitting models to data and estimating parameters. I think that this approach is very useful for the future of the field of comparative statistics for three main reasons. First, it is flexible; one can easily compare a wide range of competing models to your data. Second, it is extendable; one can create new mod-

els and automatically fit them into a preexisting framework for data analysis. Finally, it is powerful; a model fitting approach allows us to construct comparative tests that relate directly to particular biological hypotheses.

Footnotes

- 1: I assume here that you have little interest in organisms other than lizards.
- 2: And, often, concludes that we just “need more data” to get the answer that we want.
- 3: Especially in fields like genomics where multiple testing and massive Bonferroni corrections are common; one can only wonder at the legions of type II errors that are made under such circumstances.

Chapter 3: Introduction to Brownian Motion

Section 3.1: Introduction

Squamates, the group that includes snakes and lizards, is exceptionally diverse. Since sharing a common ancestor between 150 and 210 million years ago (Hedges and Kumar 2009), squamates have diversified to include species that are very large and very small; herbivores and carnivores; species with legs and species that are legless. How did that diversity of species' traits evolve? How did these characters first come to be, and how rapidly did they change to explain the diversity that we see on earth today? In this chapter, we will begin to discuss models for the evolution of species' traits.

Imagine that you want to use statistical approaches to understand how traits change through time. To do that, you need to have an exact mathematical specification of how evolution takes place. Obviously there are a wide variety of models of trait evolution, from simple to complex. For example, you might create a model where a trait starts with a certain value and has some constant probability of changing in any unit of time. Alternatively, you might make a model that is more detailed and explicit, and considers a large set of individuals in a population. You could assign genotypes to each individual and allow the population to evolve through reproduction and natural selection.

In this chapter – and in comparative methods as a whole – the models we will consider will be much closer to the first of these two models. However, there are still important connections between these simple models and more realistic models of trait evolution. (see chapter five).

In the next six chapters, I will discuss models for two different types of characters. In this chapter and chapters four, five, and six, I will consider traits that follow continuous distributions – that is, traits that can have real-numbered values. For example, body mass in kilograms is a continuous character. I will discuss the most commonly used model for these continuous characters, Brownian motion, in this chapter and the next, while chapter five covers analyses of multivariate Brownian

motion. We will go beyond Brownian motion in chapter six. In chapter seven and the chapters that immediately follow, I will cover discrete characters, characters that can occupy one of a number of distinct character states (for example, species of squamates can either be legless or have legs).

Section 3.2: Properties of Brownian Motion

We can use Brownian motion to model the evolution of a continuously valued trait through time. Brownian motion is an example of a “random walk” model because the trait value changes randomly, in both direction and distance, over any time interval. The statistical process of Brownian motion was originally invented to describe the motion of particles suspended in a fluid. To me this is a bit hard to picture, but the logic applies equally well to the movement of a large ball over a crowd in a stadium. When the ball is over the crowd, people push on it from many directions. The sum of these many small forces determine the movement of the ball. Again, the movement of the ball can be modeled using Brownian motion¹.

The core idea of this example is that the motion of the object is due to the sum of a large number of very small, random forces. This idea is a key part of biological models of evolution under Brownian motion. It is worth mentioning that even though Brownian motion involves change that has a strong random component, it is incorrect to equate Brownian motion models with models of pure genetic drift (as explained in more detail below).

Brownian motion is a popular model in comparative biology because it captures the way traits might evolve under a reasonably wide range of scenarios. However, perhaps the main reason for the dominance of Brownian motion as a model is that it has some very convenient statistical properties that allow relatively simple analyses and calculations on trees. I will use some simple simulations to show how the Brownian motion model behaves. I will then list the three critical statistical properties of Brownian motion, and explain how we can use these properties to apply Brownian motion models to phylogenetic comparative trees.

When we model evolution using Brownian motion, we are typically discussing the dynamics of the mean character value, which we will denote as \bar{z} , in a population. That is, we imagine that you can measure a sample of the individuals in a population and estimate the mean average trait value. We will denote the mean trait value at some time t as $\bar{z}(t)$. We can model the mean trait value through time with a Brownian motion process.

Brownian motion models can be completely described by two parameters. The first is the starting value of the population mean trait, $\bar{z}(0)$. This is the mean trait value that is seen in the ancestral population at the start of the simulation, before any trait change occurs. The second parameter of Brownian motion is the evolutionary rate parameter, σ^2 . This parameter determines how fast traits will randomly walk through time.

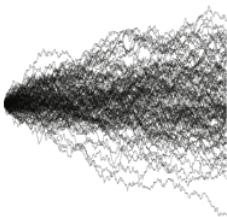

At the core of Brownian motion is the normal distribution. You might know that a normal distribution can be described by two parameters, the mean and variance. Under Brownian motion, changes in trait values over any interval of time are always drawn from a normal distribution with mean 0 and variance proportional to the product of the rate of evolution and the length of time (variance = $\sigma^2 t$). As I will show later, we can simulate change under Brownian motion model by drawing from normal distributions. Another way to say this more simply is that we can always describe how much change to expect under Brownian motion using normal distributions. These normal distributions for expected changes have a mean of zero and get wider as the time interval we consider gets longer.

A few simulations will illustrate the behavior of Brownian motion. Figure 3.1 shows sets of Brownian motion run over three different time periods ($t = 100, 500$, and 1000) with the same starting value $\bar{z}(0) = 0$ and rate parameter $\sigma^2 = 1$. Each panel of the figure shows 100 simulations of the process over that time period. You can see that the tip values look like normal distributions. Furthermore, the variance among separate runs of the process increases linearly with time. This variance among runs is greatest over the longest time intervals. It is this variance, the variation among many independent runs of the same evolutionary process, that we will consider throughout the next section.

A,

B,

C,

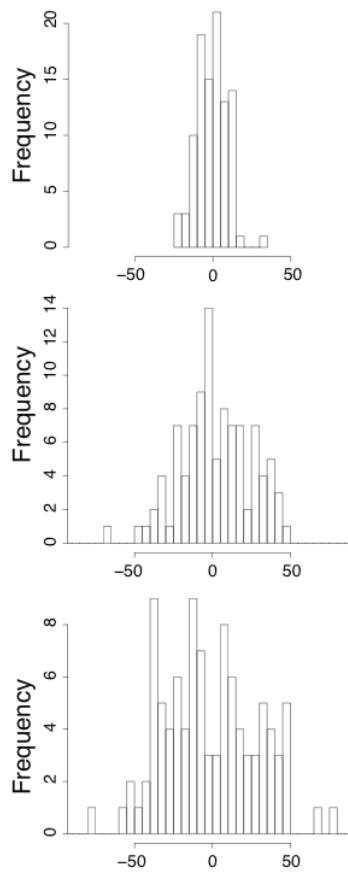

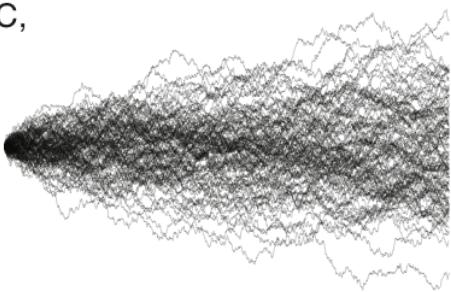

Figure 3.1. Examples of Brownian motion. Each plot shows 100 replicates of simulated Brownian motion with a common starting value and the same rate parameter $\sigma^2 = 1$. Simulations were run for three different times: (A) 10, (B) 50, and (C) 100 time units. The right-hand column shows a histogram of the distribution of ending values for each set of 100 simulations.

Imagine that we run a Brownian motion process over a given time interval many times, and save the trait values at the end of each of these simulations. We can then create a statistical distribution of these character states. It might not be obvious from figure 3.1, but the distributions of possible character states at any time point in a Brownian walk is normal. This is illustrated in figure 3.2, which shows the distribution of traits from 100,000 simulations with $\sigma^2 = 1$ and $t = 100$. The tip characters from all of these simulations follow a normal distribution with mean equal to the starting value, $\bar{z}(0) = 0$, and a variance of $\sigma^2 t = 100$.

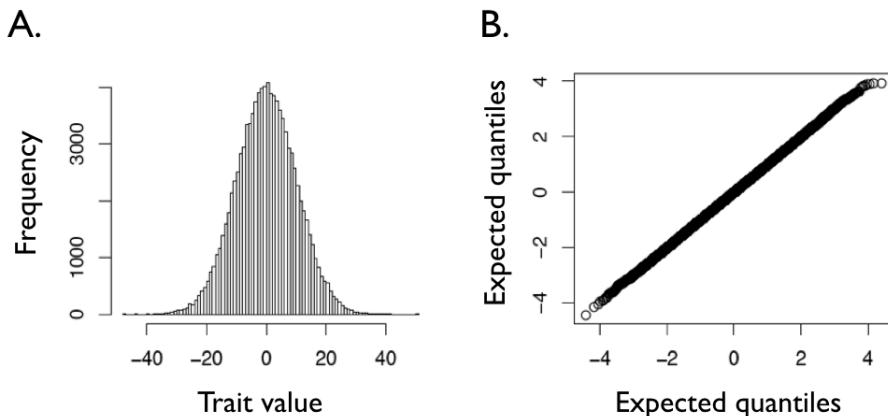

Figure 3.2. Ending character values from of 100,000 Brownian motion simulations with $\bar{z}(0) = 0$, $t = 100$, and $\sigma^2 = 1$. Panel (A) shows a histogram of the outcome of these simulations, while panel (B) shows a normal Q-Q plot for these data. If the data follow a normal distribution, the points in the Q-Q plot should form a straight line.

Figure 3.3 shows how rate parameter σ^2 affects the rate of spread of Brownian walks. The panels show sets of 100 Brownian motion simu-

lations run over 1000 time units for $\sigma^2 = 1$ (Panel A), $\sigma^2 = 5$ (Panel B), and $\sigma^2 = 25$ (Panel C). You can see that simulations with a higher rate parameter create a larger spread of trait values among simulations over the same amount of time.

If we let $\bar{z}(t)$ be the value of our character at time t , then we can derive three main properties of Brownian motion. I will list all three, then explain each in turn.

1. $E[\bar{z}(t)] = \bar{z}(0)$
2. Each successive interval of the “walk” is independent
3. $\bar{z}(t) \sim N(\bar{z}(0), \sigma^2 t)$

First, $E[\bar{z}(t)] = \bar{z}(0)$. This means that the expected value of the character at any time t is equal to the value of the character at time zero. Here the expected value refers to the mean of $\bar{z}(t)$ over many replicates. The intuitive meaning of this equation is that Brownian motion has no “trends,” and wanders equally in both positive and negative directions. If you take the mean of a large number of simulations of Brownian motion over any time interval, you will likely get a value close to $\bar{z}(0)$; as you increase the sample size, this mean will tend to get closer and closer to $\bar{z}(0)$.

Second, each successive interval of the “walk” is independent. Brownian motion is a process in continuous time, and so time does not have discrete “steps.” However, if you sample the process from time 0 to time t , and then again at time $t + \Delta t$, the change that occurs over these two intervals will be independent of one another. This is true of any two non-overlapping intervals sampled from a Brownian walk. It is worth noting that only the changes are independent, and that the value of the walk at time $t + \Delta t$ – which we can write as $\bar{z}(t + \Delta t)$ – is not independent of the value of the walk at time t , $\bar{z}(t)$. But the differences between successive steps [e.g. $\bar{z}(t) - \bar{z}(0)$ and $\bar{z}(t + \Delta t) - \bar{z}(t)$] are independent of each other and of $\bar{z}(0)$.

Finally, $\bar{z}(t) \sim N(\bar{z}(0), \sigma^2 t)$. That is, the value of $\bar{z}(t)$ is drawn from a normal distribution with mean $\bar{z}(0)$ and variance $\sigma^2 t$. As we noted above, the parameter σ^2 is important for Brownian motion models, as it describes the rate at which the process wanders through trait space. The overall variance of the process is that rate times the amount of

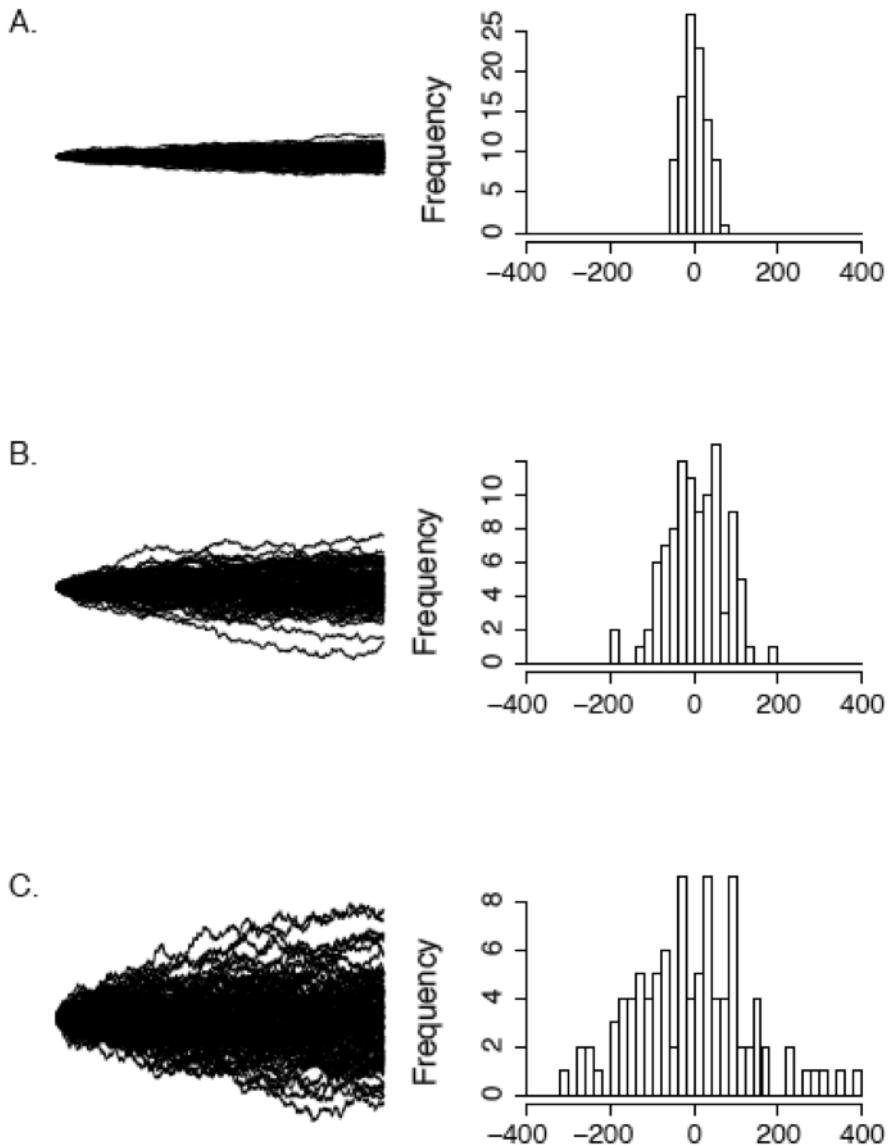

Figure 3.3. Examples of Brownian motion. Each plot shows 100 replicates of simulated Brownian motion with a common starting value and the same time interval $t = 100$. The rate parameter σ^2 varies across the panels: (A) $\sigma^2 = 1$ (B) $\sigma^2 = 10$, and (C) $\sigma^2 = 25$. The right-hand column shows a histogram of the distribution of ending values for each set of 100 simulations.

time that has elapsed.

Section 3.3: Simple Quantitative Genetics Models for Brownian Motion

Section 3.3a: Brownian motion under genetic drift

The simplest way to obtain Brownian evolution of characters is when evolutionary change is neutral, with traits changing only due to genetic drift. (e.g. Lande 1976). To show this, we will create a simple model. We will assume that a character is influenced by many genes, each of small effect, and that the value of the character does not affect fitness. Finally, we assume that mutations are random and have small effects on the character, as specified below. These assumptions probably seem unrealistic, especially if you are thinking of a trait like the body size of a lizard! But we will see later that we can also derive Brownian motion under other models, some of which involve selection.

Consider the mean value of this trait, \bar{z} , in a population with a (variance) effective population size of N_e^2 . Since there is no selection, the phenotypic character will change due only to mutations and genetic drift. We can model this process in a number of ways, but the simplest uses an “infinite alleles” model. Under this model, mutations occur randomly and have random phenotypic effects. We assume that mutations are drawn at random from a distribution with mean 0 and mutational variance σ_m^2 . This model assumes that the number of alleles is so large that there is effectively no chance of mutations happening to the same allele more than once - hence, “infinite alleles.” The alleles in the population then change in frequency through time due to genetic drift. Drift and mutation together, then, determine the dynamics of the mean trait through time.

If we were to simulate this infinite alleles model many times, we would have a set of evolved populations. These populations would, on average, have the same mean trait value, but would differ from each other. Let’s try to derive how, exactly, these populations³ evolve.

If we consider a population evolving under this model, it is not difficult

to show that the expected population phenotype after any amount of time is equal to the starting phenotype. This is because the phenotypes don't matter for survival or reproduction, and mutations are assumed to be random and symmetrical. Thus,

(eq. 3.1)

$$E[\bar{z}(t)] = \bar{z}(0)$$

Note that this equation already matches the first property of Brownian motion.

Next, we need to also consider the variance of these mean phenotypes, which we will call the between-population phenotypic variance (σ_B^2). Importantly, σ_B^2 is the same quantity we earlier described as the “variance” of traits over time – that is, the variance of mean trait values across many independent “runs” of evolutionary change over a certain time period.

To calculate σ_B^2 , we need to consider variation within our model populations. Because of our simplifying assumptions, we can focus solely on additive genetic variance within each population at some time t , which we can denote as σ_a^2 . Additive genetic variance measures the total amount of genetic variation that acts additively (e.g. contributions of each allele add together to predict the final phenotype). This excludes genetic variation involving interactions between alleles, such as dominance and epistasis (see Lynch and Walsh 1998 for a more detailed discussion). Additive genetic variance in a population will change over time due to genetic drift (which tends to decrease σ_a^2) and mutational input (which tends to increase σ_a^2). We can model the expected value of σ_a^2 from one generation to the next as (Clayton and Robertson 1955; Lande 1979, 1980).

(eq. 3.2)

$$E[\sigma_a^2(t + 1)] = (1 - \frac{1}{2N_e})E[\sigma_a^2(t)] + \sigma_m^2$$

where t is the elapsed time in generations, N_e is the effective population size, and σ_m^2 is the mutational variance. There are two parts to this equation. The first, $(1 - \frac{1}{2N_e})E[\sigma_a^2(t)]$, shows the decrease in additive genetic variance each generation due to genetic drift. The rate of

decrease depends on effective population size, N_e , and the current level of additive variation. The second part of the equation describes how additive genetic variance increases due to new mutations (σ_m^2) each generation.

If we assume that we know the starting value at time 0, σ_{aStart}^2 , we can calculate the expected additive genetic variance at any time t as:

(eq. 3.3)

$$E[\sigma_a^2(t)] = \left(1 - \frac{1}{2N_e}\right)^t [\sigma_{aStart}^2 - 2N_e\sigma_m^2] + 2N_e\sigma_m^2$$

Note that the first term in the above equation, $\left(1 - \frac{1}{2N_e}\right)^t$, goes to zero as t becomes large. This means that additive genetic variation in the evolving populations will eventually reach an equilibrium between genetic drift and new mutations, so that additive genetic variation stops changing from one generation to the next. We can find this equilibrium by taking the limit of equation 3.3 as t becomes large.

(eq. 3.4)

$$\lim_{t \rightarrow \infty} E[\sigma_a^2(t)] = 2N_e\sigma_m^2$$

Thus the equilibrium genetic variance depends on both population size and mutational input.

We can now derive the between-population phenotypic variance at time t , $\sigma_B^2(t)$. We will assume that σ_a^2 is at equilibrium and thus constant (equation 3.4). Mean trait values in independently evolving populations will diverge from one another. Skipping some calculus, after some time period t has elapsed, the expected among-population variance will be (from Lande 1976):

(eq. 3.5)

$$\sigma_B^2(t) = \frac{t\sigma_a^2}{N_e}$$

Substituting the equilibrium value of σ_a^2 from equation 3.4 into equation 3.5 gives (Lande 1979, 1980):

(eq. 3.6)

$$\sigma_B^2(t) = \frac{t\sigma_a^2}{N_e} = \frac{t \cdot 2N_e\sigma_m^2}{N_e} = 2t\sigma_m^2$$

This equation states that the variation among two diverging populations depends on twice the time since they have diverged and the rate of mutational input. Notice that for this model, the amount of variation among populations is independent of both the starting state of the populations and their effective population size. This model predicts, then, that long-term rates of evolution are dominated by the supply of new mutations to a population.

Even though we had to make particular specific assumptions for that derivation, Lynch and Hill (1986) show that equation 3.6 is a general result that holds under a range of models, even those that include dominance, linkage, nonrandom mating, and other processes. Equation 3.6 is somewhat useful, but we cannot often measure the mutational variance σ_m^2 for any natural populations (but see Turelli 1984). By contrast, we sometimes do know the heritability of a particular trait. Heritability describes the proportion of total genetic variation within a population (σ_w^2) that is due to additive genetic effects (σ_a^2): $h^2 = \frac{\sigma_a^2}{\sigma_w^2}$.

We can calculate the expected trait heritability for the infinite alleles model at mutational equilibrium. Substituting equation 3.4, we find that:

(eq. 3.7)

$$h^2 = \frac{2N_e\sigma_m^2}{\sigma_w^2}$$

So that:

(eq. 3.8)

$$\sigma_m^2 = \frac{h^2\sigma_w^2}{2N_e}$$

Here, h^2 is heritability, N_e the effective population size, and σ_w^2 the within-population phenotypic variance, which differs from σ_a^2 because it includes all sources of variation within populations, including both

non-additive genetic effects and environmental effects. Substituting this expression for σ_w^2 into equation 3.6, we have:

(eq. 3.9)

$$\sigma_B^2(t) = 2\sigma_m^2 t = \frac{h^2 \sigma_w^2 t}{N_e}$$

So, after some time interval t , the mean phenotype of a population has an expected value equal to the starting value, and a variance that depends positively on time, heritability, and trait variance, and negatively on effective population size.

To derive this result, we had to make particular assumptions about normality of new mutations that might seem quite unrealistic. It is worth noting that if phenotypes are affected by enough mutations, the central limit theorem guarantees that the distribution of phenotypes within populations will be normal – no matter what the underlying distribution of those mutations might be. We also had to assume that traits are neutral, a more dubious assumption that we relax below – where we will also show that there are other ways to get Brownian motion evolution than just genetic drift!

Note, finally, that this quantitative genetics model predicts that traits will evolve under a Brownian motion model. Thus, our quantitative genetics model has the same statistical properties of Brownian motion. We only need to translate one parameter: $\sigma^2 = h^2 \sigma_w^2 / N_e$.

Section 3.3b: Brownian motion under selection

We have shown that it is possible to relate a Brownian motion model directly to a quantitative genetics model of drift. In fact, there is some temptation to equate the two, and conclude that traits that evolve like Brownian motion are not under selection. However, this is incorrect. More specifically, an observation that a trait is evolving as expected under Brownian motion is not equivalent to saying that that trait is not under selection. This is because characters can also evolve as a Brownian walk even if there is strong selection – as long as selection acts in particular ways that maintain the properties of the Brownian motion model.

In general, the path followed by population mean trait values under mutation, selection, and drift depend on the particular way in which these processes occur. A variety of such models are considered by Hansen and Martins (1996). They identify three very different models that include selection where mean traits still evolve under an approximately Brownian model. Here I present univariate versions of the Hansen-Martins models, for simplicity; consult the original paper for multivariate versions. Note that all of these models require that the strength of selection is relatively weak, or else genetic variation of the character will be depleted by selection over time and the dynamics of trait evolution will change.

One model assumes that populations evolve due to directional selection, but the strength and direction of selection varies randomly from one generation to the next. We model selection each generation as being drawn from a normal distribution with mean 0 and variance σ_s^2 . Similar to our drift model, populations will again evolve under Brownian motion. However, in this case the Brownian motion parameters have a different interpretation:

(eq. 3.10)

$$\sigma_B^2 = \left(\frac{h^2 \sigma_W^2}{N_e} + \sigma_s^2 \right) t$$

In the particular case where variation in selection is much greater than variation due to drift, then:

(eq. 3.11)

$$\sigma_B^2 \approx \sigma_s^2$$

That is, when selection is (on average) much stronger than drift, the rate of evolution is completely dominated by the selection term. This is not that far fetched, as many studies have shown selection in the wild that is both stronger than drift and commonly changing in both direction and magnitude from one generation to the next.

In a second model, Hansen and Martins (1996) consider a population subject to strong stabilizing selection for a particular optimal value, but where the position of the optimum itself changes randomly according to a Brownian motion process. In this case, population means can

again be described by Brownian motion, but now the rate parameter reflects movement of the optimum rather than the action of mutation and drift. Specifically, if we describe movement of the optimum by a Brownian rate parameter σ_E^2 , then:

(eq. 3.12)

$$\sigma_B^2 \approx \sigma_E^2$$

To obtain this result we must assume that there is at least a little bit of stabilizing selection (at least on the order of $1/t_{ij}$ where t_{ij} is the number of generations separating pairs of populations; Hansen and Martins 1996).

Again in this case, the population is under strong selection in any one generation, but long-term patterns of trait change can be described by Brownian motion. The rate of the random walk is totally determined by the action of selection rather than drift.

The important take-home point from both of these models is that the pattern of trait evolution through time under this model still follows a Brownian motion model, even though changes are dominated by selection and not drift. In other words, Brownian motion evolution does not imply that characters are not under selection!

Finally, Hansen and Martins (1996) consider the situation where populations evolve following a trend. In this case, we get evolution that is different from Brownian motion, but shares some key attributes. Consider a population under constant directional selection, s , so that:

(eq. 3.13)

$$E[\bar{z}(t+1)] = \bar{z}(t) + h^2 s$$

The variance among populations due to genetic drift after a single generation is then:

(eq. 3.14)

$$\sigma_B^2 = \frac{h^2 \sigma_w^2}{N_e}$$

Over some longer period of time, traits will evolve so that they have expected mean trait value that is normal with mean:

(eq. 3.15)

$$E[\bar{z}(t)] = t \cdot (h^2 s)$$

We can also calculate variance among species as:

(eq. 3.16)

$$\sigma_B^2(t) = \frac{h^2 \sigma_w^2 t}{N_e}$$

Note that the variance of this process is exactly identical to the variance among populations in a pure drift model (equation 3.9). Selection only changes the expectation for the species mean (of course, we assume that variation within populations and heritability are constant, which will only be true if selection is quite weak). Furthermore, with comparative methods, we are often considering a set of species and their traits in the present day, in which case they will all have experienced the same amount of evolutionary time (t) and have the same expected trait value. In fact, equations 3.14 and 3.16 are exactly the same as what we would expect under a pure-drift model in the same population, but starting with a trait value equal to $\bar{z}(0) = t \cdot (h^2 s)$. That is, from the perspective of data only on living species, these two pure drift and linear selection models are statistically indistinguishable. The implications of this are striking: we can never find evidence for trends in evolution studying only living species (Slater et al. 2012b).

In summary, we can describe three very different ways that traits might evolve under Brownian motion – pure drift, randomly varying selection, and varying stabilizing selection – and one model, constant directional selection, which creates patterns among extant species that are indistinguishable from Brownian motion. And there are more possible models out there that predict the same patterns. One can never tell these models apart by evaluating the qualitative pattern of evolution across species - they all predict the same pattern of Brownian motion evolution. The details differ, in that the models have Brownian motion rate parameters that differ from one another and relate to measurable quantities like population size and the strength of selection. Only by knowing something about these parameters can we distinguish among these possible scenarios.

You might notice that none of these “Brownian” models are particularly detailed, especially for modeling evolution over long time scales. You might even complain that these models are unrealistic. It is hard to imagine a case where a trait might be influenced only by random mutations of small effect over many alleles, or where selection would act in a truly random way from one generation to the next for millions of years. And you would be right! However, there are tremendous statistical benefits to using Brownian models for comparative analyses. Many of the results derived in this book, for example, are simple under Brownian motion but much more complex and different under other models. And it is also the case that some (but not all) methods are robust to modest violations of Brownian motion, in the same way that many standard statistical analyses are robust to minor variations of the assumptions of normality. In any case, we will proceed with models based on Brownian motion, keeping in mind these important caveats.

Section 3.4: Brownian motion on a phylogenetic tree

We can use the basic properties of Brownian motion model to figure out what will happen when characters evolve under this model on the branches of a phylogenetic tree. First, consider evolution along a single branch with length t_1 (Figure 3.4A). In this case, we can model simple Brownian motion over time t_1 and denote the starting value as $\bar{z}(0)$. If we evolve with some rate parameter σ_B^2 , then:

(eq. 3.17)

$$E[\bar{z}(t)] \sim N(\bar{z}(0), \sigma_B^2 t_1)$$

Now consider a small section of a phylogenetic tree including two species and an ancestral stem branch (Figure 3.4B). Assume a character evolves on that tree under Brownian motion, again with starting value $\bar{z}(0)$ and rate parameter σ_B^2 . First consider species a. The mean trait in that species \bar{x}_a evolves under Brownian motion from the ancestor to species a over a total time of $t_1 + t_2$. Thus,

(eq. 3.18)

$$\bar{x}_a \sim N[\bar{z}(0), \sigma_B^2(t_1 + t_2)]$$

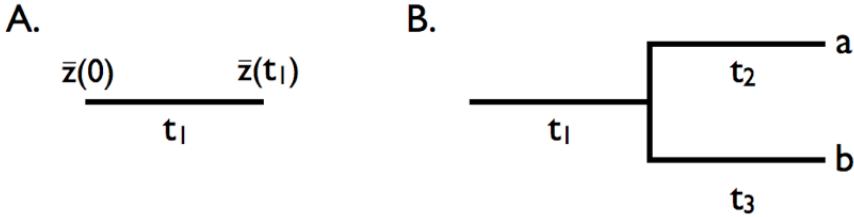

Figure 3.4. Brownian motion on a simple tree. A. Evolution in a single lineage over time period t_1 . B. Evolution on a phylogenetic tree relating species a and b, with branch lengths as given by t_1 , t_2 , and t_3 .

Similarly for species b, over a total time of $t_1 + t_3$

(eq. 3.19)

$$\bar{x}_b \sim N[\bar{z}(0), \sigma_B^2(t_1 + t_3)]$$

However, \bar{x}_a and \bar{x}_b are not independent of each other. Instead, the two species share one branch in common (along branch 1). Each tip trait value can be thought of as an ancestral value plus the sum of two evolutionary changes: one (from branch 1) that is shared between the two species and one that is unique (branch 2 for species a and branch 3 for species b). In this case, mean trait values \bar{x}_a and \bar{x}_b will share similarity due to their shared evolutionary history. We can describe this similarity by calculating the covariance between the traits of species a and b. We note that:

(eq. 3.20)

$$\begin{aligned}\bar{x}_a &= \Delta\bar{x}_1 + \Delta\bar{x}_2 \\ \bar{x}_b &= \Delta\bar{x}_1 + \Delta\bar{x}_3\end{aligned}$$

Where $\Delta\bar{x}_1$, $\Delta\bar{x}_2$, and $\Delta\bar{x}_3$ represent evolution along the three branches in the tree, are all normally distributed with mean zero and variances $\sigma^2 t_1$, $\sigma^2 t_2$, and $\sigma^2 t_3$, respectively. \bar{x}_a and \bar{x}_b are sums of normal random variables and are themselves normal. The covariance of these two terms is simply the variance of their shared term:

(eq. 3.21)

$$cov(\bar{x}_a, \bar{x}_b) = var(\Delta\bar{x}_1) = \sigma_B^2 t_1$$

It is also worth noting that we can describe the trait values for the two species as a single draw from a multivariate normal distribution. Each trait has the same expected value, $\bar{z}(0)$, and the two traits have a variance-covariance matrix:

(eq. 3.22)

$$\begin{bmatrix} \sigma^2(t_1 + t_2) & \sigma^2 t_1 \\ \sigma^2 t_1 & \sigma^2(t_1 + t_3) \end{bmatrix} = \sigma^2 \begin{bmatrix} t_1 + t_2 & t_1 \\ t_1 & t_1 + t_3 \end{bmatrix} = \sigma^2 \mathbf{C}$$

The matrix \mathbf{C} in equation 3.22 is commonly encountered in comparative biology, and will come up again in this book. We will call this matrix the phylogenetic variance-covariance matrix. This matrix has a special structure. For phylogenetic trees with n species, this is an $n \times n$ matrix, with each row and column corresponding to one of the n taxa in the tree. Along the diagonal are the total distances of each taxon from the root of the tree, while the off-diagonal elements are the total branch lengths shared by particular pairs of taxa. For example, $\mathbf{C}(1, 2)$ and $\mathbf{C}(2, 1)$ – which are equal because the matrix \mathbf{C} is always symmetric – is the shared phylogenetic path length between the species in the first row – here, species a – and the species in the second row – here, species b. Under Brownian motion, these shared path lengths are proportional to the phylogenetic covariances of trait values. A full example of a phylogenetic variance-covariance matrix for a small tree is shown in Figure 3.5. This multivariate normal distribution completely describes the expected statistical distribution of traits on the tips of a phylogenetic tree if the traits evolve according to a Brownian motion model.

Section 3.5: Multivariate Brownian motion

The Brownian motion model we described above was for a single character. However, we often want to consider more than one character at once. This requires the use of multivariate models. The situation is more complex than the univariate case – but not much! In this section I will derive the expectation for a set of (potentially correlated) traits evolving together under a multivariate Brownian motion model.

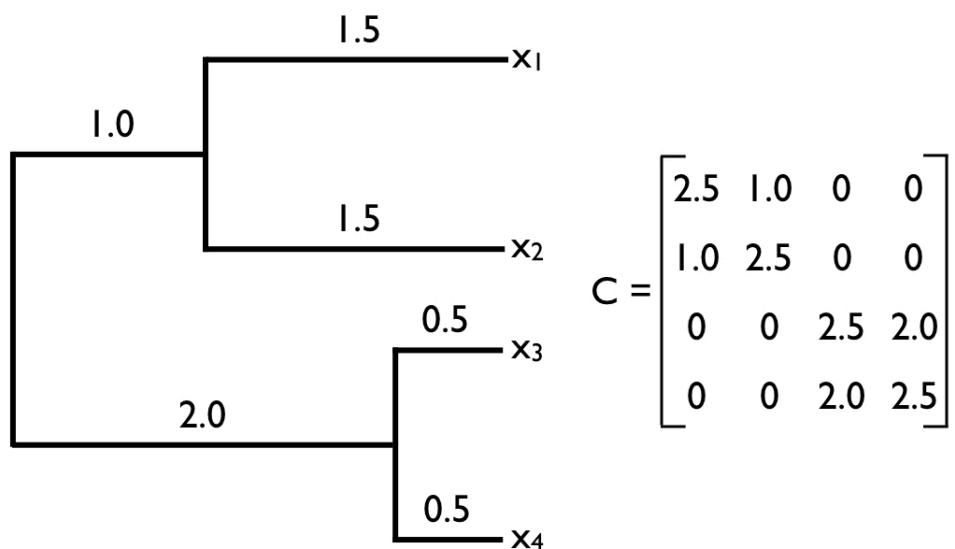

Figure 3.5. Example of a phylogenetic tree (left) and its associated phylogenetic variance-covariance matrix \mathbf{C} (right).

Character values across species can covary because of phylogenetic relationships, because different characters tend to evolve together, or both. Fortunately, we can generalize the model described above to deal with both of these types of covariation. To do this, we must combine two variance-covariance matrices. The first one, \mathbf{C} , we have already seen; it describes the variances and covariances across *species* for single traits due to shared evolutionary history along the branches of a phylogenetic tree. The second variance-covariance matrix, which we can call \mathbf{R} , describes the variances and covariances across *traits* due to their tendencies to evolve together. For example, if a species of lizard gets larger due to the action of natural selection, then many of its other traits, like head and limb size, will get larger too due to allometry. The diagonal entries of the matrix \mathbf{R} will provide our estimates of σ_i^2 , the net rate of evolution, for each trait, while off-diagonal elements, σ_{ij} , represent evolutionary covariances between pairs of traits. We will denote number of species as n and the number of traits as m , so that \mathbf{C} is $n \times n$ and \mathbf{R} is $m \times m$.

Our multivariate model of evolution has parameters that can be described by an $m \times 1$ vector, \mathbf{a} , containing the starting values for each trait – $\bar{z}_1(0)$, $\bar{z}_2(0)$, and so on, up to $\bar{z}_m(0)$, and an $m \times m$ matrix, \mathbf{R} , described above. This model has m parameters for \mathbf{a} and $m \cdot (m + 1)/2$ parameters for \mathbf{R} , for a total of $m \cdot (m + 3)/2$ parameters.

Under our multivariate Brownian motion model, the joint distribution of all traits across all species still follows a multivariate normal distribution. We find the variance-covariance matrix that describes all characters across all species by combining the two matrices \mathbf{R} and \mathbf{C} into a single large matrix using the Kroeneker product:

(eq. 3.23)

$$\mathbf{V} = \mathbf{R} \otimes \mathbf{C}$$

This matrix \mathbf{V} is $n \cdot m \times n \cdot m$, and describes the variances and covariances of all traits across all species.

We can return to our example of evolution along a single branch (Figure 3.4a). Imagine that we have two characters that are evolving under a multivariate Brownian motion model. We state the parameters of the model as:

(eq. 3.24)

$$\mathbf{a} = \begin{bmatrix} \bar{z}_1(0) \\ \bar{z}_2(0) \end{bmatrix}$$

$$\mathbf{R} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} \\ \sigma_{12} & \sigma_2^2 \end{bmatrix}$$

For a single branch, $\mathbf{C} = [t_1]$, so:

(eq. 3.25)

$$\mathbf{V} = \mathbf{R} \otimes \mathbf{C} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} \\ \sigma_{12} & \sigma_2^2 \end{bmatrix} \otimes [t_1] = \begin{bmatrix} \sigma_1^2 t_1 & \sigma_{12} t_1 \\ \sigma_{12} t_1 & \sigma_2^2 t_1 \end{bmatrix}$$

The two traits follow a multivariate normal distribution with mean \mathbf{a} and variance-covariance matrix \mathbf{V} .

For the simple tree in figure 3.4b,

(eq. 3.26)

$$\mathbf{V} = \mathbf{R} \otimes \mathbf{C} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} \\ \sigma_{12} & \sigma_2^2 \end{bmatrix} \otimes \begin{bmatrix} t_1 + t_2 & t_1 & t_1 \\ t_1 & t_1 + t_2 & t_1 + t_3 \end{bmatrix}$$

$$= \begin{bmatrix} \sigma_1^2(t_1 + t_2) & \sigma_{12}(t_1 + t_2) & \sigma_1^2 t_1 & \sigma_{12} t_1 \\ \sigma_{12}(t_1 + t_2) & \sigma_2^2(t_1 + t_2) & \sigma_{12} t_1 & \sigma_2^2 t_1 \\ \sigma_1^2 t_1 & \sigma_{12} t_1 & \sigma_1^2(t_1 + t_3) & \sigma_{12}(t_1 + t_3) \\ \sigma_{12} t_1 & \sigma_2^2 t_1 & \sigma_{12}(t_1 + t_3) & \sigma_2^2(t_1 + t_3) \end{bmatrix}$$

Thus, the four trait values (two traits for two species) are drawn from a multivariate normal distribution with mean $a = [\bar{z}_1(0), \bar{z}_1(0), \bar{z}_2(0), \bar{z}_2(0)]$ and the variance-covariance matrix shown above.

Both univariate and multivariate Brownian motion models result in traits that follow multivariate normal distributions. This is statistically convenient, and in part explains the popularity of Brownian models in comparative biology.

Section 3.6: Simulating Brownian motion on trees

To simulate Brownian motion evolution on trees, we use the three properties of the model described above. For each branch on the tree, we can draw from a normal distribution (for a single trait) or a multivariate normal distribution (for more than one trait) to determine the evolution that occurs on that branch. We can then add these evolutionary changes together to obtain character states at every node and tip of the tree.

I will illustrate one such simulation for the simple tree depicted in figure 3.4b. We first set the ancestral character state to be $\bar{z}(0)$, which will then be the expected value for all the nodes and tips in the tree. This tree has three branches, so we draw three values from normal distributions. These normal distributions have mean zero and variances that are given by the rate of evolution and the branch length of the tree, as stated in equation 3.1. Note that we are modeling changes on these branches, so even if $\bar{z}(0) \neq 0$ the values for changes on branches are drawn from a distribution with a mean of zero. In the case of the tree in Figure 3.1, $x_1 \sim N(0, \sigma^2 t_1)$. Similarly, $x_2 \sim N(0, \sigma^2 t_2)$ and $x_3 \sim N(0, \sigma^2 t_3)$. If I set $\sigma^2 = 1$ for the purposes of this example, I might obtain $x_1 = -1.6$, $x_2 = 0.1$, and $x_3 = -0.3$. These values represent the evolutionary changes that occur along branches in the simulation. To calculate trait values for species, we add: $x_a = +x_1+x_2 = 0-1.6+0.1 = -1.5$, and $x_b = +x_1+x_3 = 0-1.6+-0.3 = -1.9$.

This simulation algorithm works fine but is actually more complicated than it needs to be, especially for large trees. We already know that x_a and x_b come from a multivariate normal distribution with known mean vector and variance-covariance matrix. So, as a simple alternative, we can simply draw a vector from this distribution, and our tip values will have exactly the same statistical properties as if they were simulated on a phylogenetic tree. These two methods for simulating character evolution on trees are exactly equivalent to one another. In our small example, this alternative is not too much simpler than just adding the branches - but in some circumstances it is much easier to draw from a multivariate normal distribution.

Section 3.7: Summary

In this chapter, I introduced Brownian motion as a model of trait evolution. I first connected Brownian motion to a model of neutral genetic drift for traits that have no effect on fitness. However, as I demonstrated, Brownian motion can result from a variety of other models, some of which include natural selection. For example, traits will follow Brownian motion under selection if the strength and direction of selection varies randomly through time. In other words, testing for a Brownian motion model with your data tells you nothing about whether or not the trait is under selection.

There is one general feature of all models that evolve in a Brownian way: they involve the action of a large number of very small “forces” pushing on characters. No matter the particular distribution of these small effects or even what causes them, if you add together enough of them you will obtain a normal distribution of outcomes and, sometimes, be able to model this process using Brownian motion. The main restriction might be the unbounded nature of Brownian motion – species are expected to become more and more different through time, without any limit, which must be unrealistic over very long time scales. We will deal with this issue in later chapters.

In summary, Brownian motion is mathematically tractable, and has convenient statistical properties. There are also some circumstances under which one would expect traits to evolve under a Brownian model. However, as we will see later in the book, one should view Brownian motion as an assumption that might not hold for real data sets.

Footnotes

1: More formally, the ball will move in two-dimensional Brownian motion, which describe movement both across and up and down the stadium rows. But if you consider just the movement in one direction - say, the distance of the ball from the field - then this is a simple single dimensional Brownian motion process as described here.

2: Variance effective population size is the effective population size of a

model population with random mating, no substructure, and constant population size that would have quantitative genetic properties equal to our actual population. All of this is a bit beyond the scope of this book (but see Templeton 2006). But writing N_e instead of N allows us to develop the model without worrying about all of the extra assumptions we would have to make about how individuals mate and how populations are distributed over time and space.

- 3: In this book, we will typically consider variation among species rather than populations. However, we will also always assume that species are made up of one population, and so we can apply the same mathematical equations across species in a phylogenetic tree.
- 4: In some cases in the literature, the magnitude of trait change is expressed in within-population phenotypic standard deviations, $\sqrt{\sigma_w^2}$, per generation (Estes and Arnold 2007; e.g. Harmon et al. 2010). In that case, since dividing a random normal deviate by x is equivalent to dividing its variance by x^2 , we have $\sigma^2 = h^2/N_e$.

Chapter 4: Fitting Brownian Motion Models to Single Characters

Section 4.1: Introduction

Mammals come in a wide variety of shapes and sizes. Some species are incredibly tiny. For example, the bumblebee bat, weighing in at 2 g, competes for the title of smallest mammal with the slightly lighter (but also slightly longer) Etruscan shrew (Hill 1974). Other species are huge, as anyone who has encountered a blue whale knows. Body size is important as a biological variable because it predicts so many other aspect of an animal's life, from the physiology of heat exchange to the biomechanics of locomotion. Thus, the rate at which body size evolves is of great interest among mammalian biologists. Throughout this chapter, I will discuss the evolution of body size (and, eventually, territory size) across different species of mammals. The data I will analyze is taken from Garland (1992).

Sometimes one might be interested in calculating the rate of evolution of a particular character like body size in a certain clade, say, mammals. You have a phylogenetic tree with branch lengths that are proportional to time, and data on the phenotypes of species on the tips of that tree. It is usually a good idea to log-transform your data if they involve a measurement from a living thing (see Box 4.1, below). If we assume that the character has been evolving under a Brownian motion model, we have two parameters to estimate: $\bar{z}(0)$, the starting value for the Brownian motion model – equivalent to the ancestral state of the character at the root of the tree – and σ^2 , the diffusion rate of the character. It is this latter parameter that is commonly considered as the rate of evolution for comparative approaches¹.

Box 4.1: Biology under the log

One general rule for continuous traits in biology is to carry out a log-transformation (usually natural log, base e , denoted \ln) of your data

before undergoing any analysis. This also applies to comparative data. There are two main reasons for this, one statistical and the other biological. The statistical reason is that many methods assume that variables follow normal distributions. One can observe that, in general, measurements of species' traits have a distribution that is skewed to the right. A log-transformation will often result in trait distributions that are closer to normal. But why is this the case? The answer is related to the biological reason for log-transformation. When you log transform a variable, the new scale for that variable is a ratio scale, so that a certain differences between points reflects a constant ratio of the two numbers represented by the points. So, for example, if any two numbers are separated by 0.693 units on a natural log scale, one will be exactly two times the other. Ratio scales make sense for living things because it is usually percentage changes rather than absolute changes that matter. For example, a change in body size of 1 mm might matter a lot for a termite, but be irrelevant for an elephant; whereas a change in body size of 50% might be expected to matter for them both.

Section 4.2: Estimating rates using independent contrasts

The information required to estimate evolutionary rates is efficiently summarized in the early (but still useful) phylogenetic comparative method of independent contrasts (Felsenstein 1985). Independent contrasts summarize the amount of character change across each node in the tree, and can be used to estimate the rate of character change across a phylogeny. There is also a simple mathematical relationship between contrasts and maximum-likelihood rate estimates that I will discuss below.

We can understand the basic idea behind independent contrasts if we think about the branches in the phylogenetic tree as the historical “pathways” of evolution. Each branch on the tree represents a lineage that was alive at some time in the history of the Earth, and during that time experienced some amount of evolutionary change. We can imagine trying to measure that change initially by comparing sister

taxa. We can compare the trait values of the two sister taxa by finding the difference in their trait values, and then compare that to the total amount of time they have had to evolve that difference. By doing this for all sister taxa in the tree, we will get an estimate of the average rate of character evolution (4.1A). But what about deeper nodes in the tree? We could use other non-sister species pairs, but then we would be counting some branches in the tree of life more than once (Figure 4.1B). Instead, we use a “pruning algorithm,” (Felsenstein 1985, Felsenstein (2004)) chopping off pairs of sister taxa to create a smaller tree (Figure 4.1C). Eventually, all of the nodes in the tree will be trimmed off – and the algorithm will finish. Independent contrasts provides a way to generalize the approach of comparing sister taxa so that we can quantify the rate of evolution throughout the whole tree.

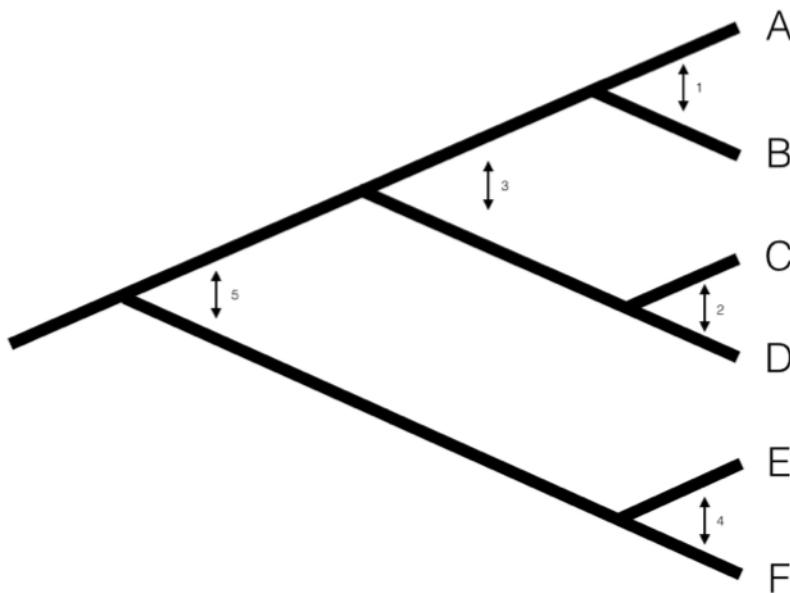

Figure 4.1. Pruning algorithm that can be used to identify five independent contrasts for a tree with six species (from Felsenstein 1985). The numbered order in this figure is only one of several possibilities that work; one can also prune the tree in the order 1, 2, 4, 3, 5 and get identical results.

A more precise algorithm describing how phylogenetic independent contrasts are calculated is provided in Box 4.2, below (from Felsenstein

1985). Each contrast can be described as an estimate of the direction and amount of evolutionary change across the nodes in the tree. PICs are calculated from the tips of the tree towards the root, as differences between trait values at the tips of the tree and/or calculated average values at internal nodes. The differences themselves are sometimes called “raw contrasts” (Felsenstein 1985). These raw contrasts will all be statistically independent of each other under a wide range of evolutionary models. In fact, as long as each lineage in a phylogenetic tree evolves independently of every other lineage, regardless of the evolutionary model, the raw contrasts will be independent of each other. However, people almost never use raw contrasts because they are not identically distributed; each raw contrast has a different expected distribution that depends on the model of evolution and the branch lengths of the tree. In particular, under Brownian motion we expect more change on longer branches of the tree. Felsenstein (1985) divided the raw contrasts by their expected standard deviation under a Brownian motion model, resulting in standardized contrasts. These standardized contrasts are, under a BM model, both independent and identically distributed, and can be used in a variety of statistical tests. Note that we must assume a Brownian motion model in order to standardize the contrasts; results derived from the contrasts, then, depend on this Brownian motion assumption.

Box 4.2: Algorithm for PICs

One can calculate PICs using the algorithm from Felsenstein (1985). I reproduce this algorithm below. Keep in mind that this is an iterative algorithm – you repeat the five steps below once for each contrast, or $n - 1$ times over the whole tree (see Figure 4.1C as an example).

1. Find two tips on the phylogeny that are adjacent (say nodes i and j) and have a common ancestor, say node k . Note that the choice of which node is i and which is j is arbitrary. As you will see, we will have to account for this “arbitrary direction” property of PICs in any analyses where we use them to do certain analyses!

2. Compute the raw contrast, the difference between their two tip values: (eq. 4.1)

$$c_{ij} = x_i - x_j$$

- Under a Brownian motion model, c_{ij} has expectation zero and variance proportional to $v_i + v_j$.
3. Calculate the standardized contrast by dividing the raw contrast by its variance (eq. 4.2)

$$s_{ij} = \frac{c_{ij}}{v_i + v_j} = \frac{x_i - x_j}{v_i + v_j}$$

- Under a Brownian motion model, this contrast follows a normal distribution with mean zero and variance equal to the Brownian motion rate parameter σ^2 .
4. Remove the two tips from the tree, leaving behind only the ancestor k , which now becomes a tip. Assign it the character value: (eq. 4.3)

$$x_k = \frac{(1/v_i)x_i + (1/v_j)x_j}{1/v_1 + 1/v_j}$$

- It is worth noting that x_k is a weighted average of x_i and x_j , but does not represent an ancestral state reconstruction, since the value is only influenced by species that descend directly from that node and not other relatives.
5. Lengthen the branch below node k by increasing its length from v_k to $v_k + v_i v_j / (v_i + v_j)$. This accounts for the uncertainty in assigning a value to x_k .

As mentioned above, we can apply the algorithm of independent contrasts to learn something about rates of body size evolution in mammals. We have a phylogenetic tree with branch lengths as well as body mass estimates for 49 species (Figure 4.2). If we ln-transform mass and then apply the method above to our data on mammal body size, we obtain a set of 48 standardized contrasts. A histogram of these contrasts is shown as Figure 4.2 (data from Garland 1992).

Histogram of body mass PICs

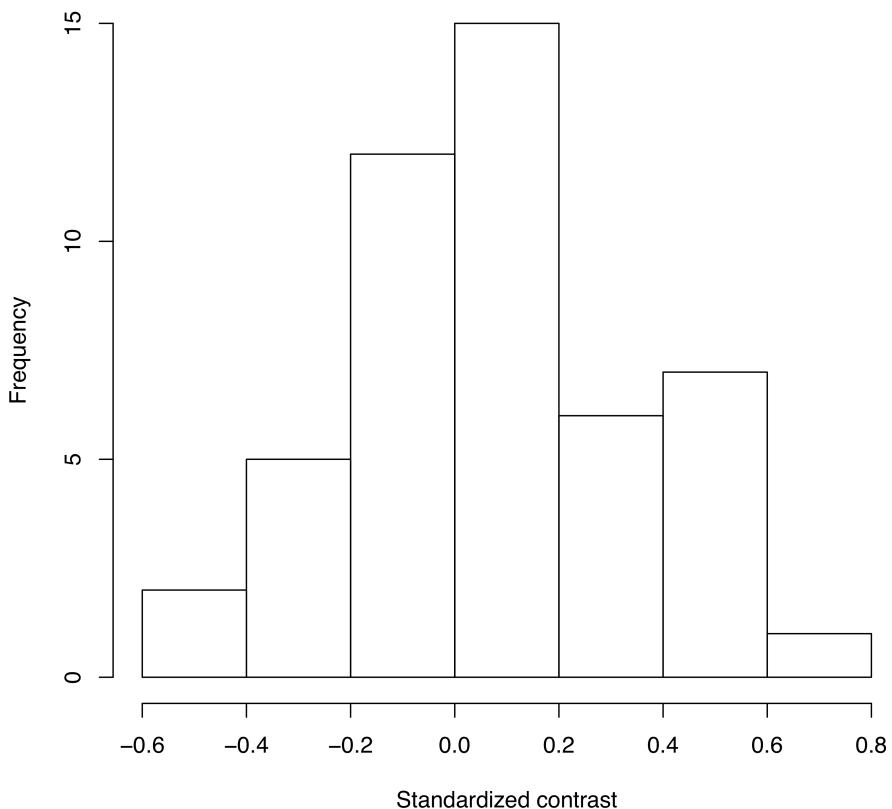

Figure 4.2. Histogram of PICs for ln-transformed mammal body mass on a phylogenetic tree with branch lengths in millions of years (from Garland 1992).

Note that each contrast is an amount of change, $x_i - x_j$, divided by a branch length, $v_i + v_j$, which is a measure of time. Thus, PICs from a single trait can be used to estimate σ^2 , the rate of evolution under a Brownian model. The PIC estimate of the evolutionary rate is:

(eq. 4.4)

$$\hat{\sigma}_{PIC}^2 = \frac{\sum s_{ij}^2}{n - 1}$$

That is, the PIC estimate of the evolutionary rate is the average of the $n - 1$ squared contrasts. This sum is taken over all s_{ij} , the standardized independent contrast across all (i, j) pairs of sister branches in the phylogenetic tree. For a fully bifurcating tree with n tips, there are exactly $n - 1$ such pairs. If you are statistically savvy, you might note that this formula looks a bit like a variance. In fact, if we state that the contrasts have a mean of 0 (which they must because Brownian motion has no overall trends), then this is a formula to estimate the variance of the contrasts.

If we calculate the mean sum of squared contrasts for the mammal body mass data, we obtain a rate estimate of $\hat{\sigma}_{PIC}^2 = 0.09$. We can put this into words: if we simulated mammalian body mass evolution under this model, we would expect the variance across replicated runs to increase by 0.09 per million years. Or, in more concrete terms, if we think about two lineages diverging from one another for a million years, we can draw changes in ln-body mass for both of them from a normal distribution with a variance of 0.09. Their difference, then, which is the amount of expected divergence, will be normal with a variance of $2 \cdot 0.09 = 0.18$. Thus, with 95% confidence, we can expect the two species to differ maximally by two standard deviations of this distribution, $2 \cdot \sqrt{0.18} = 0.85$. Since we are on a log scale, this amount of change corresponds to a factor of $e^{2.68} = 2.3$, meaning that one species will commonly be about twice as large (or small) as the other after just one million years.

Section 4.3: Estimating rates using maximum likelihood

We can also estimate the evolutionary rate by finding the maximum-likelihood parameter values for a Brownian motion model fit to our data. Recall that ML parameter values are those that maximize the likelihood of the data given our model (see Chapter 2).

We already know that under a Brownian motion model, tip character states are drawn from a multivariate normal distribution with a variance-covariance matrix, \mathbf{C} , that is calculated based on the branch lengths and topology of the phylogenetic tree (see Chapter 3). We can calculate the likelihood of obtaining the data under our Brownian motion model using a standard formula for the likelihood of drawing from a multivariate normal distribution:

(eq. 4.5)

$$L(\mathbf{x}|\bar{z}(0), \sigma^2, \mathbf{C}) = \frac{e^{-1/2(\mathbf{x}-\bar{z}(0)\mathbf{1})^\top(\sigma^2\mathbf{C})^{-1}(\mathbf{x}-\bar{z}(0)\mathbf{1})}}{\sqrt{(2\pi)^n \det(\sigma^2\mathbf{C})}}$$

Here, our model parameters are σ^2 and $\bar{z}(0)$, the root trait value. x is an $n \times 1$ vector of trait values for the n tip species in the tree, with species in the same order as \mathbf{C} , and $\mathbf{1}$ is an $n \times 1$ column vector of ones. Note that $(\sigma^2\mathbf{C})^{-1}$ is the matrix inverse of the matrix $\sigma^2\mathbf{C}$.

As an example, with the mammal data, we can calculate the likelihood for a model with parameter values $\sigma^2 = 1$ and $\bar{z}(0) = 0$. We need to work with ln-likelihoods ($\ln L$), both because the value here is so small and to facilitate future calculations, so: $\ln L(\mathbf{x}|\bar{z}(0), \sigma^2, \mathbf{C}) = -116.2$.

To find the ML estimates of our model parameters, we need to find the parameter values that maximize that function. One (not very efficient) way to do this is to calculate the likelihood across a wide range of parameter values. One can then visualize the resulting likelihood surface and identify the maximum of the likelihood function. For example, the likelihood surface for the mammal body size data given a Brownian motion model is shown in Figure 4.3. Note that this surface has a peak around $\sigma^2 = 0.09$ and $\bar{z}(0) = 4$. Inspecting the matrix of

ML values, we find the highest ln-likelihood (-78.05) at $\sigma^2 = 0.089$ and $\bar{z}(0) = 4.65$.

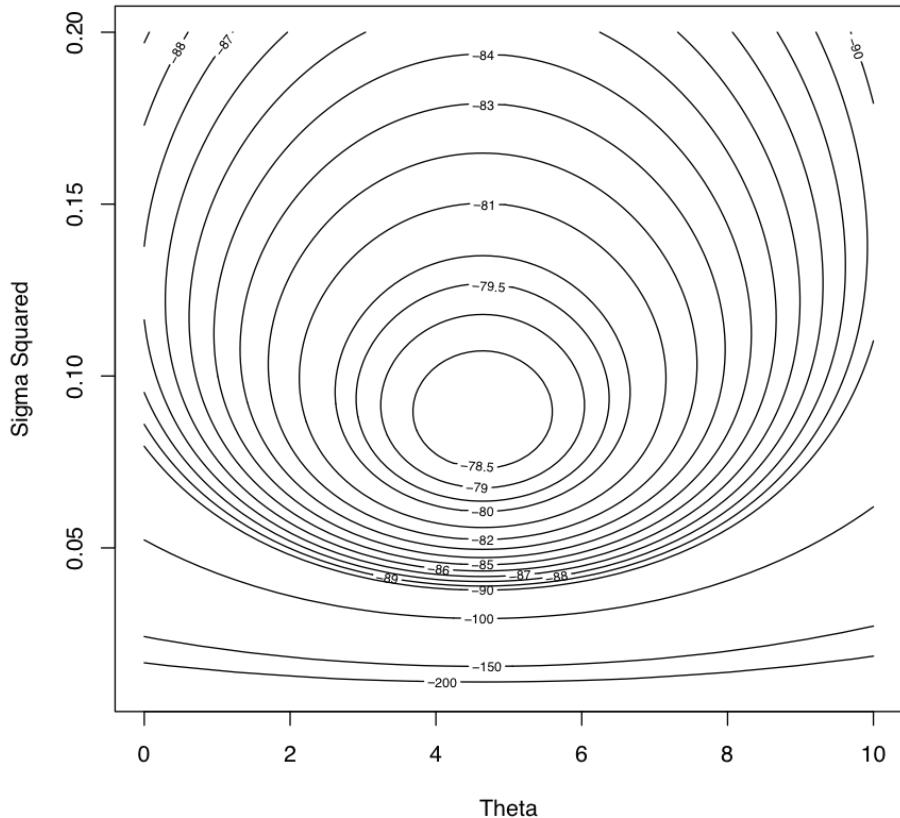

Figure 4.3. Likelihood surface for the evolution of mammalian body mass using the data from Garland (1992).

The calculation described above is inefficient, because we have to calculate likelihoods at a wide range of parameter values that are far from the optimum. A better strategy involves the use of optimization algorithms, a well-developed field of mathematical analysis (Nocedal and Wright 2006). These algorithms differ in their details, but we can illustrate how they work with a general example. Imagine that you are

near Mt. St. Helens, and you are tasked with finding the peak of that mountain. It is foggy, but you can see the area around your feet and have an accurate altimeter. One strategy is to simply look at the slope of the mountain where you are standing, and climb uphill. If the slope is steep, you probably still are far from the top, and should climb fast; if the slope is shallow, you might be near the top of the mountain. It may seem obvious that this will get you to a local peak, but perhaps not the highest peak of Mt. St. Helens. Mathematical optimization schemes have this potential difficulty as well, but use some tricks to jump around in parameter space and try to find the overall highest peak as they climb. Details of actual optimization algorithms are beyond the scope of this book; for more information, see Nocedal and Wright (2006).

One simple example is based on Newton's method of optimization [as implemented, for example, by the `r` function `nlm()`]. We can use this algorithm to quickly find accurate ML estimates².

Using optimization algorithms we find a ML solution at $\hat{\sigma}_{ML}^2 = 0.08804487$ and $\hat{z}(0) = 4.640571$, with $\ln L = -78.04942$. Importantly, the solution can be found with only 10 likelihood calculations; this is the value of good optimization algorithms. I have plotted the path through parameter space taken by Newton's method when searching for the optimum in Figure 4.4. Notice two things: first, that the function starts at some point and heads uphill on the likelihood surface until an optimum is found; and second, that this calculation requires many fewer steps (and much less time) than calculating the likelihood for a wide range of parameter values.

Using an optimization algorithm also has the added benefit of providing (approximate) confidence intervals for parameter values based on the Hessian of the likelihood surface. This approach assumes that the shape of the likelihood surface in the immediate vicinity of the peak can be approximated by a quadratic function, and uses the curvature of that function, as determined by the Hessian, to approximate the standard errors of parameter values (Burnham and Anderson 2003). If the surface is strongly peaked, the SEs will be small, while if the surface is very broad, the SEs will be large. For example, the likelihood surface around the ML values for mammal body size evolution has a Hessian

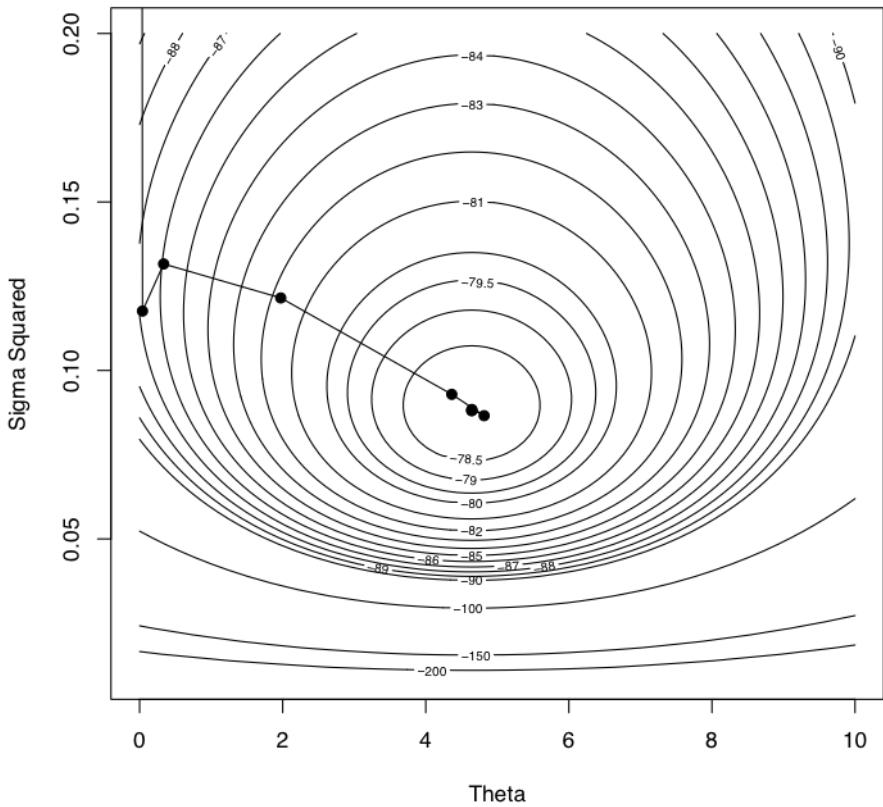

Figure 4.4. Likelihood surface for the evolution of mammalian body mass using the data from Garland (1992). Shown here is the path taken by the optimization algorithm to find the peak of the likelihood surface. The last five steps of this ten-step algorithm are too close together to be seen in this figure.

of:

(eq. 4.6)

$$H = \begin{bmatrix} 314.6 & -0.0026 \\ -0.0026 & 0.99 \end{bmatrix}$$

This gives standard errors of 0.13 (for $\hat{\sigma}_{ML}^2$) and 0.72 [for $\hat{z}(0)$]. If we assume the error around these estimates is approximately normal, we can create confidence estimates by adding and subtracting twice the standard error. We then obtain 95% CIs of $0.06 - 0.11$ (for $\hat{\sigma}_{ML}^2$) and $3.22 - 6.06$ [for $\hat{z}(0)$].

The danger in optimization algorithms is that one can sometimes get stuck on local peaks. More elaborate algorithms repeated for multiple starting points can help solve this problem, but are not needed for simple Brownian motion on a tree as considered here. Numerical optimization is a difficult problem in phylogenetic comparative methods, especially for software developers.

In the particular case of fitting Brownian motion to trees, it turns out that even our fast algorithm for optimization was unnecessary. In this case, the maximum-likelihood estimate for each of these two parameters can be calculated analytically (O'Meara et al. 2006a).

(eq. 4.7)

$$\hat{z}(0) = (\mathbf{1}\mathbf{C}^{-1}\mathbf{1})^{-1}(\mathbf{1}\mathbf{C}^{-1}\mathbf{x})$$

and:

(eq. 4.8)

$$\hat{\sigma}_{ML}^2 = \frac{(\mathbf{x} - \hat{z}(0)\mathbf{1})\mathbf{C}^{-1}(\mathbf{x} - \hat{z}(0)\mathbf{1})}{n}$$

where n is the number of taxa in the tree, \mathbf{C} is the $n \times n$ variance-covariance matrix under Brownian motion for tip characters given the phylogenetic tree, x is an $n \times 1$ vector of trait values for tip species in the tree, $\mathbf{1}$ is an $n \times 1$ column vector of ones, $\hat{z}(0)$ is the estimated root state for the character, and $\hat{\sigma}_{ML}^2$ is the estimated net rate of evolution.

Applying this approach to mammal body size, we obtain estimates that are exactly the same as our results from numeric optimization:

$\hat{\sigma}_{ML}^2 = 0.088$ and $\hat{z}(0) = 4.64$.

Equation (4.8) is biased, and will consistently estimate rates of evolution that are a little too small; an unbiased version based on restricted maximum likelihood (REML) and used by Garland (1992) and others is:

(eq. 4.9)

$$\hat{\sigma}_{REML}^2 = \frac{(\mathbf{x} - \hat{z}(0)\mathbf{1})\mathbf{C}^{-1}(\mathbf{x} - \hat{z}(0)\mathbf{1})}{n - 1}$$

This correction changes our estimate of the rate of body size in mammals from $\hat{\sigma}_{ML}^2 = 0.088$ to $\hat{\sigma}_{REML}^2 = 0.090$. Equation 4.8 is exactly identical to the estimated rate of evolution calculated using the average squared independent contrast, described above; that is, $\hat{\sigma}_{PIC}^2 = \hat{\sigma}_{REML}^2$. In fact, PICs are a formulation of a REML model. The “restricted” part of REML refers to the fact that these methods calculate likelihoods based on a transformed set of data where the effect of nuisance parameters has been removed. In this case, the nuisance parameter is the estimated root state $\hat{z}(0)$ ³.

For the mammal body size example, we can further explore the difference between REML and ML in terms of statistical confidence intervals using likelihoods based on the contrasts. We assume, again, that the contrasts are all drawn from a normal distribution with mean 0 and unknown variance. If we again use Newton’s method for optimization, we find a maximum REML log-likelihood of -10.3 at $\hat{\sigma}_{REML}^2 = 0.090$. This returns a 1×1 matrix for the Hessian with a value of 2957.8, corresponding to a SE of 0.018. This slightly larger SE corresponds to 95% CI for $\hat{\sigma}_{REML}^2$ of 0.05 – 0.13.

In the context of comparative methods, REML has two main advantages. First, PICs treat the root state of the tree as a nuisance parameter. We typically have very little information about this root state, so that can be an advantage of the REML approach. Second, PICs are easy to calculate for very large phylogenetic trees because they do not require the construction (or inversion!) of any large variance-covariance matrices. This is important for big phylogenetic trees. Imagine that we had a phylogenetic tree of all vertebrates (~60,000 species) and wanted to calculate the rate of body size evolution. To use standard maximum

likelihood, we have to calculate \mathbf{C} , a matrix with $60,000 \times 60,000 = 3.6$ billion entries, and invert it to calculate \mathbf{C}^{-1} . To calculate PICs, by contrast, we only have to carry out on the order of 120,000 operations. Thankfully, there are now pruning algorithms to quickly calculate likelihoods for large trees under a variety of different models (see, e.g., FitzJohn 2012, Freckleton (2012), and Ho and Ané (2014)).

Section 4.4: Bayesian approach to evolutionary rates

Finally, we can also use a Bayesian approach to fit Brownian motion models to data and to estimate the rate of evolution. This approach differs from the ML approach in that we will use explicit priors for parameter values, and then run an MCMC to estimate posterior distributions of parameter estimates. To do this, we will modify the basic algorithm for Bayesian MCMC (see Chapter 2) as follows:

1. Sample a set of starting parameter values, σ^2 and $\bar{z}(0)$ from their prior distributions. For this example, we can set our prior distribution as uniform between 0 and 0.5 for σ^2 and uniform from 0 to 10 for $\bar{z}(0)$.
2. Given the current parameter values, select new proposed parameter values using the proposal density $Q(p'|p)$. For both parameter values, we will use a uniform proposal density with width w_p , so that: (eq. 4.10)

$$Q(p'|p) \sim U\left(p - \frac{w_p}{2}, p + \frac{w_p}{2}\right)$$

3. Calculate three ratios:

- a. The prior odds ratio, R_{prior} . This is the ratio of the probability of drawing the parameter values p and p' from the prior. Since our priors are uniform, this is always 1.
- b. The proposal density ratio, $R_{proposal}$. This is the ratio of probability of proposals going from p to p' and the reverse. We have already declared a symmetrical proposal density, so that $Q(p'|p) = Q(p|p')$ and $R_{proposal} = 1$.

- c. The likelihood ratio, $R_{likelihood}$. This is the ratio of probabilities of the data given the two different parameter values. We can calculate these probabilities from equation 4.5 above. (eq. 4.11)

$$R_{likelihood} = \frac{L(p'|D)}{L(p|D)} = \frac{P(D|p')}{P(D|p)}$$

- Find the acceptance ratio, R_{accept} , which is product of the prior odds, proposal density ratio, and the likelihood ratio. In this case, both the prior odds and proposal density ratios are 1, so $R_{accept} = R_{likelihood}$.
- Draw a random number x from a uniform distribution between 0 and 1. If $x < R_{accept}$, accept the proposed value of both parameters; otherwise reject, and retain the current value of the two parameters.
- Repeat steps 2-5 a large number of times.

Using the mammal body size data, I ran an MCMC with 10,000 generations, discarding the first 1000 as burn-in. Sampling every 10 generations, I obtain parameter estimates of $\hat{\sigma}_{bayes}^2 = 0.10$ (95% credible interval: $0.066 - 0.15$) and $\hat{z}(0) = 3.5$ (95% credible interval: $2.3 - 5.3$; Figure 4.5).

Note that the parameter estimates from all three approaches (REML, ML, and Bayesian) were similar. Even the confidence/credible intervals varied a little bit but were of about the same size in all three cases. All of the approaches above are mathematically related and should, in general, return similar results. One might place higher value on the Bayesian credible intervals over confidence intervals from the Hessian of the likelihood surface, for two reasons: first, the Hessian leads to an estimate of the CI under certain conditions that may or may not be true for your analysis; and second, Bayesian credible intervals reflect overall uncertainty better than ML confidence intervals (see chapter 2).

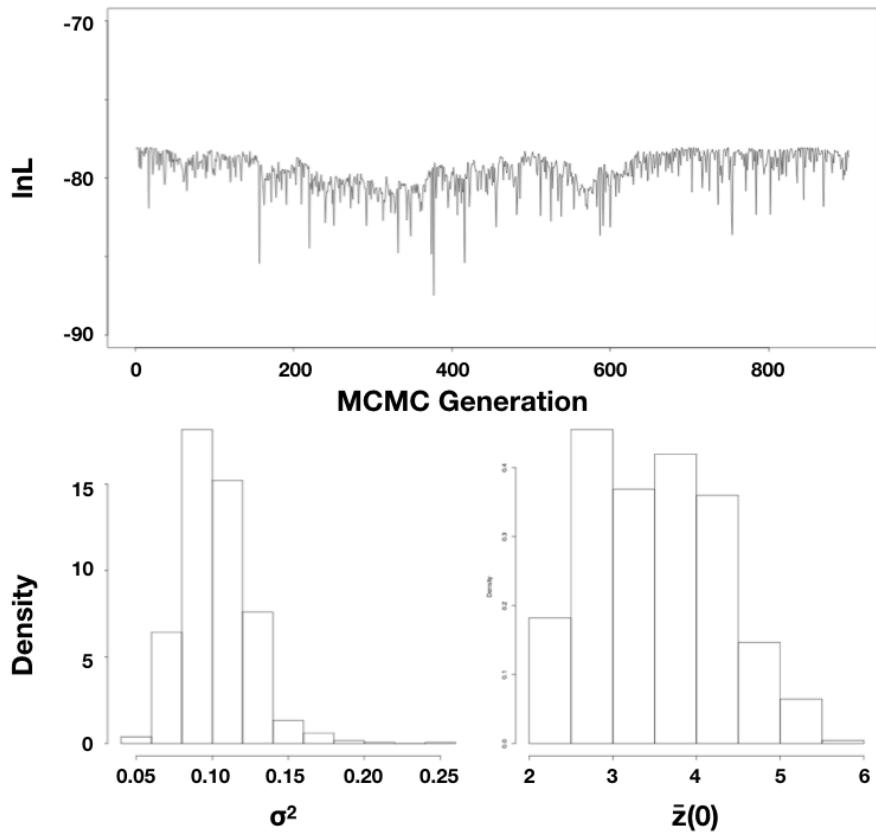

Figure 4.5. Bayesian analysis of body size evolution in mammals. Figure shows the likelihood profile (A) and posterior distributions for model parameters $\hat{\sigma}_{bayes}^2$ (B) and $\hat{z}(0)$ (C).

Section 4.5: Summary

By fitting a Brownian motion model to phylogenetic comparative data, one can estimate the rate of evolution of a single character. In this chapter, I demonstrated three approaches to estimating that rate: PICs, maximum likelihood, and Bayesian MCMC. In the next chapter, we will discuss other models of evolution that can be fit to continuous characters on trees.

Footnotes

1: Throughout this chapter, when I say “rate” I will mean the Brownian motion parameter σ^2 . This is a little different from “traditional” estimates of evolutionary rate, like those estimated by paleontologists. For example, one might have measurements of trait in a series of fossils representing an evolutionary lineage sampled at different time periods. By calculating the amount of change over a given time interval, one can estimate an evolutionary rate. These rates can be expressed as Darwins (defined as the log-difference in trait values divided by time in years) or Haldanes (defined as the difference in trait values scaled by their standard deviations divided by time in generations). Both types of rates have been calculated from both fossil data and contemporary time-series data on evolution from both islands and lab experiments. Such rates best capture evolutionary trends, where the mean value of a trait is changing in a consistent way through time (for more information see review in Harmon 2014). Rates estimated by Brownian motion are a different type of “rate”, and some care must be taken to compare the two (see, e.g., Gingerich 1983).

2: Note that there are more complicated optimization algorithms that are useful for more difficult problems in comparative methods. In the case presented here, where the surface is smooth and has a single peak, almost any algorithm will work.

3:PICs are a transformation of the original data in which all information about the root state has been removed; our idea of what that root state might be has no effect on calculations using PICs. One can calculate the likelihood for the PIC REML method by assuming all of the

standardized PICs are drawn from a normal distribution (eq. 4.5) with mean 0 and variance $\hat{\sigma}_{REML}^2$ (eq. 4.8). Alternatively, one can estimate the variance of the PICs directly, keeping in mind that one must use a mean of zero (eq. 4.4). These two methods give exactly the same results.

Chapter 5: Fitting Brownian Motion Models to Multiple Characters

Section 5.1: Introduction

As discussed in Chapter 4, body size is one of the most important traits of an animal. Body size has a close relationship to almost all of an animal's ecological interactions, from whether it is a predator or prey to its metabolic rate. If that is true, we should be able to use body size to predict other traits that might be related through shared evolutionary processes. We need to understand how the evolution of body size is correlated with other species' characteristics.

A wide variety of hypotheses can be framed as tests of correlations between continuously varying traits across species. For example, is the body size of a species related to its metabolic rate? How does the head length of a species relate to overall size, and do deviations from this relationship relate to an animal's diet? These questions and others like them are of interest to evolutionary biologists because they allow us to test hypotheses about the factors in influencing character evolution over long time scales. These types of approaches allow us to answer some of the classic "why" questions in biology. Why are elephants so large? Why do some species of crocodilians have longer heads than others? If we find a correlation between two characters, we might suspect that there is a causal relationship between our two variables of interest - or perhaps that both of our measured variables share a common cause.

In this chapter, we will use the example of home range size, which is the area where an animal carries out its day-to-day activities. We will again use data from Garland (1992) and test for a relationship between body size and the size of a mammal's home range. I will describe methods for using empirical data to estimate the parameters of multivariate Brownian motion models. I will then describe a model-fitting approach to test for evolutionary correlations. This model fitting approach is simple but not commonly used. Finally, I will review two common statistical approaches to test for evolutionary correlations, phylogenetic independent contrasts and phylogenetic generalized least squares, and describe their relationship to model-fitting approaches.

Section 5.2: What is evolutionary correlation?

There is sometimes a bit of confusion among beginners as to what, exactly, we are doing when we carry out a comparative method, especially when testing for character correlations. Common language that comparative methods “control for phylogeny” or “remove the phylogeny from the data” is not necessarily enlightening or even always accurate. Another common suggestion is that species are not statistically independent and that we must account for that with comparative methods. While accurate, I still don’t think this statement fully captures the tree-thinking perspective enabled by comparative methods. In this section, I will use the particular example of correlated evolution to try to illustrate the power of comparative methods and how they differ from standard statistical approaches that do not use phylogenies.

In statistics, two variables can be correlated with one another. We might refer to this as a *standard correlation*. When two traits are correlated, it means that given the value of one trait – say, body size in mammals – one can predict the value of another – like home range area. Correlations can be positive (large values of x are associated with large values of y) or negative (large values of x are associated with small values of y). A surprisingly wide variety of hypotheses in biology can be tested by evaluating correlations between characters.

In comparative biology, we are often interested more specifically in *evolutionary correlations*. Evolutionary correlations occur when two traits tend to evolve together due to processes like mutation, genetic drift, or natural selection. If there is an evolutionary correlation between two characters, it means that we can predict the magnitude and direction of changes in one character given knowledge of evolutionary changes in another. Just like standard correlations, evolutionary correlations can be positive (increases in trait x are associated with increases in y) or negative (decreases in x are associated with increases in y).

We can now contrast standard correlations, testing the relationships between trait values across a set of species, with evolutionary correlations - where evolutionary changes in two traits are related to each other. This is a key distinction, because phylogenetic relatedness alone can lead to a relationship between two variables that are not, in fact,

evolving together (Figure 5.1; also see Felsenstein 1985). In such cases, standard correlations will, correctly, tell us that one can predict the value of trait y by knowing the value of trait x , at least among extant species; but we would be misled if we tried to make any evolutionary causal inference from this pattern. In the example of Figure 5.1, we can only predict x from y because the value of trait x tells us which clade the species belongs to, which, in turn, allows reasonable prediction of y . In fact, this is a classical example of a case where correlation is not causation: the two variables are only correlated with one another because both are related to phylogeny.

If we want to test hypotheses about trait evolution, we should specifically test evolutionary correlations¹. If we find a relationship among the independent contrasts for two characters, for example, then we can infer that changes in each character are related to changes in the other – an inference that is much closer to most biological hypotheses about why characters might be related. In this case, then, we can think of statistical comparative methods as focused on disentangling patterns due to phylogenetic relatedness from patterns due to traits evolving in a correlated manner.

Section 5.3: Modeling the evolution of correlated characters

We can model the evolution of multiple (potentially correlated) continuous characters using a multivariate Brownian motion model. This model is similar to univariate Brownian motion (see chapter 3), but can model the evolution of many characters at the same time. As with univariate Brownian motion, trait values change randomly in both direction and distance over any time interval. Here, though, these changes are drawn from multivariate normal distributions². Multivariate Brownian motion can encompass the situation where each character evolves independently of one another, but can also describe situations where characters evolve in a correlated way.

We can describe multivariate Brownian motion with a set of parameters that are described by \mathbf{a} , a vector of phylogenetic means for a set of r characters:

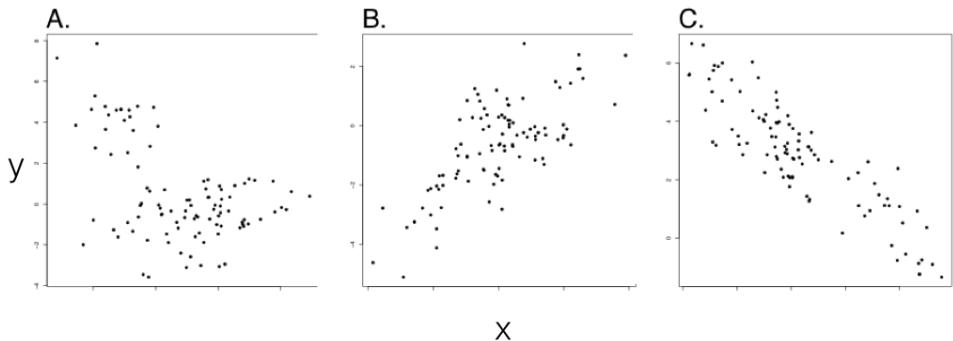

Figure 5.1. Examples from simulations of pure birth trees ($b = 1$) with $n = 100$ species. Plotted points represent character values for extant species in each clade. In all three panels, $\sigma_x^2 = \sigma_y^2 = 1$. σ_{xy}^2 varies with $\sigma_{xy}^2 = 0$ (panel A), $\sigma_{xy}^2 = 0.8$ (panel B), and $\sigma_{xy}^2 = -0.8$ (panel C). Note the (apparent) negative correlation in panel A, which can be explained by phylogenetic relatedness of species within two clades. Only panels B and C show data with an evolutionary correlation. However, this would be difficult or impossible to conclude without using comparative methods.

(eq. 5.1)

$$\mathbf{a} = [\bar{z}_1(0) \quad \bar{z}_2(0) \quad \dots \quad \bar{z}_r(0)]$$

This vector represents the starting point in r -dimensional space for our random walk. In the context of comparative methods, this is the character measurements for the lineage at the root of the tree. Additionally, we have an evolutionary rate matrix \mathbf{R} :

(eq. 5.2)

$$\mathbf{R} = \begin{bmatrix} \sigma_1^2 & \sigma_{21} & \dots & \sigma_{n1} \\ \sigma_{21} & \sigma_2^2 & \dots & \vdots \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{1n} & \dots & \dots & \sigma_{rn}^2 \end{bmatrix}$$

Here, the rate parameter for each axis (σ_i^2) is along the matrix diagonal. Off-diagonal elements represent evolutionary covariances between pairs of axes (note that $\sigma_{ij} = \sigma_{ji}$). It is worth noting that each individual character evolves under a Brownian motion process. Covariances among characters, though, potentially make this model distinct from one where each character evolves independently of all the others (Figure 5.2).

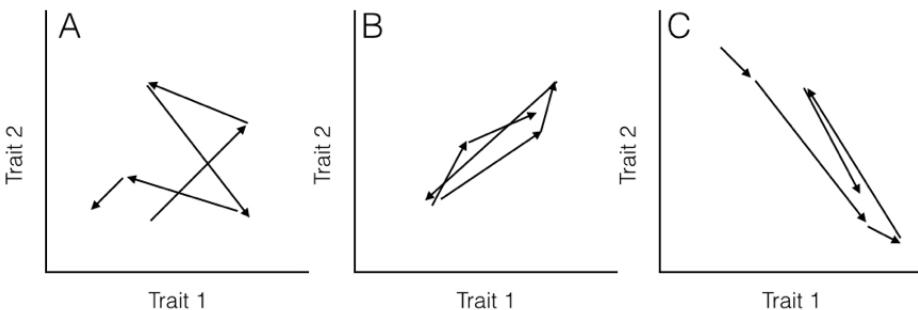

Figure 5.2. Hypothetical pathways of evolution (arrows) for (A) two uncorrelated traits, (B) two traits evolving with a positive covariance, and (C) two traits evolving with a negative covariance. Note that in (B), when trait 1 gets larger trait 2 also gets larger, but in (C) positive changes in trait 1 are paired with negative changes in trait 2.

When you have data for multiple continuous characters across many species along with a phylogenetic tree, you can fit a multivariate Brownian motion model to the data, as discussed in Chapter 3.

To calculate the likelihood, we can use the fact that, under our multivariate Brownian motion model, the joint distribution of all traits across all species has a multivariate normal distribution. Following Chapter 3, we find the variance-covariance matrix that describes that model by combining the two matrices \mathbf{R} and \mathbf{C} into a single large matrix using the Kroeneker product:

(eq. 5.3)

$$\mathbf{V} = \mathbf{R} \otimes \mathbf{C}$$

This matrix \mathbf{V} is $nr \times nr$. We can then substitute \mathbf{V} for \mathbf{C} in equation (4.5) to calculate the likelihood:

(eq. 5.4)

$$L(\mathbf{x}_{nr} | \mathbf{a}, \mathbf{R}, \mathbf{C}) = \frac{e^{-1/2(\mathbf{x}_{nr} - \mathbf{D} \cdot \mathbf{a})^\top (\mathbf{V})^{-1} (\mathbf{x}_{nr} - \mathbf{D} \cdot \mathbf{a})}}{\sqrt{(2\pi)^{nm} \det(\mathbf{V})}}$$

Here \mathbf{D} is an $nr \times r$ design matrix where each element \mathbf{D}_{ij} is 1 if $(j-1) \cdot n < i \leq j \cdot n$ and 0 otherwise. \mathbf{x}_{nr} is a single vector with all trait values for all species, listed so that the first n elements in the vector are trait 1, the next n are for trait 2, and so on:

(eq. 5.5)

$$\mathbf{x}_{nr} = [x_{11} \quad x_{12} \quad \dots \quad x_{1n} \quad x_{21} \quad \dots \quad x_{nr}]$$

We can find the value of the likelihood at its maximum by calculating $L(\mathbf{x}_{nr} | \mathbf{a}, \mathbf{R}, \mathbf{C})$ using eq. 5.4 and an optimization routine to find the MLE.

Alternatively, one can calculate this MLE solution directly. Equations for estimating $\hat{\mathbf{a}}$ (the estimated vector of phylogenetic means for all characters) and $\hat{\mathbf{R}}$ (the estimated evolutionary rate matrix) are (Revell and Harmon 2008, Hohenlohe and Arnold (2008)):

(eq. 5.6)

$$\hat{\mathbf{a}} = [(\mathbf{1}\mathbf{C}^{-1}\mathbf{1})^{-1}(\mathbf{1}\mathbf{C}^{-1}\mathbf{X})]^\top$$

(eq. 5.7)

$$\hat{\mathbf{R}} = \frac{(\mathbf{X} - \mathbf{1}\hat{\mathbf{a}})^\top \mathbf{C}^{-1} (\mathbf{X} - \mathbf{1}\hat{\mathbf{a}})}{n}$$

Note here that we use \mathbf{X} to denote the n (species) $\times r$ (traits) matrix of all traits across all species. Note the similarity between these multivariate equations (5.6 and 5.7) and their univariate equivalents (equations 4.6 and 4.7).

Section 5.4: Testing for evolutionary correlations

There are many ways to test for evolutionary correlations between two characters. Traditional methods like PICs and PGLS work great for testing evolutionary regression, which is very similar to testing for evolutionary correlations. However, when using those methods the connection to actual models of character evolution can remain opaque. Thus, I will first present approaches to test for correlated evolution based on model selection using AIC and Bayesian analysis. I will then return to “standard” methods for evolutionary regression at the end of the chapter.

Section 5.4a: Testing for character correlations using maximum likelihood and AIC

To test for an evolutionary correlation between two characters, we are really interested in the elements in the matrix \mathbf{R} . For two characters, x and y , \mathbf{R} can be written as:

(eq. 5.8)

$$\mathbf{R} = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} \\ \sigma_{xy} & \sigma_y^2 \end{bmatrix}$$

We are interested in the parameter σ_{xy} - the evolutionary covariance - and whether it is equal to zero (no correlation) or not. One simple

way to test this hypothesis is to set up two competing hypotheses and compare them to each other. One hypothesis (H_1) is that the traits evolve independently of each other, and another (H_2) that the traits evolve with some covariance σ_{xy} . We can write these two rate matrices as:

(eq. 5.9)

$$\mathbf{R}_{H_1} = \begin{bmatrix} \sigma_x^2 & 0 \\ 0 & \sigma_y^2 \end{bmatrix} \quad \mathbf{R}_{H_2} = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} \\ \sigma_{xy} & \sigma_y^2 \end{bmatrix}$$

We can calculate an ML estimate of the parameters in \mathbf{R}_{H_2} using equation 5.4. The maximum likelihood estimate of \mathbf{R}_{H_1} can be obtained by noting that, if character evolution is independent across all characters, then both σ_x^2 and σ_y^2 can be obtained by treating each character separately and using equations from chapter 3 to solve for each. It turns out that the ML estimates for σ_x^2 and σ_y^2 are always exactly the same for H_1 and H_2 .

To compare these two models, we calculate the likelihood of each using equation 5.5. We can then compare these two likelihoods using either a likelihood ratio test or by comparing AICc scores (see chapter 2).

For the mammal example, we can consider the two traits of (ln-transformed) body size and home range size (Garland 1992). These two characters have a positive correlation using standard regression analysis ($r = 0.27$), and a linear regression is significant ($P = 0.0001$; Figure 5.3). If we fit a multivariate Brownian motion model to these data, considering home range as trait 1 and body mass as trait 2, we obtain the following parameter estimates:

(eq. 5.10)

$$\hat{\mathbf{a}}_{H_2} = \begin{bmatrix} 2.54 \\ 4.64 \end{bmatrix} \quad \hat{\mathbf{R}}_{H_2} = \begin{bmatrix} 0.24 & 0.10 \\ 0.10 & 0.09 \end{bmatrix}$$

Note the positive off-diagonal element in the estimated \mathbf{R} matrix, suggesting a positive evolutionary correlation between these two traits. This model corresponds to hypothesis 2 above, and has a log-likelihood of $\ln L = -164.0$. If we fit a model with no correlation between the two traits, we obtain:

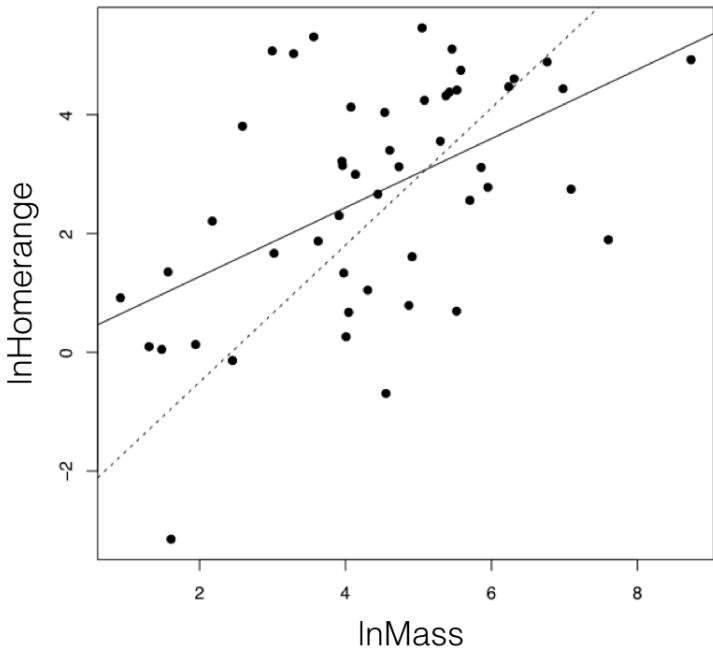

Figure 5.3. The relationship between mammal body mass and home-range size. To illustrate the effect of accounting for a tree, I plot a solid line for the regression line from a standard analysis, and dotted line from PGLS, which uses the phylogenetic tree. These methods are discussed in more detail in the next section.

(eq. 5.11)

$$\hat{\mathbf{a}}_{H_2} = \begin{bmatrix} 2.54 \\ 4.64 \end{bmatrix} \quad \hat{\mathbf{R}}_{H_2} = \begin{bmatrix} 0.24 & 0 \\ 0 & 0.09 \end{bmatrix}$$

It is worth noting again that only the estimates of the evolutionary correlation were affected by this model restriction; all other parameter estimates remain the same. This model has a smaller (more negative) log-likelihood of $\ln L = -180.5$.

A likelihood ratio test gives $\Delta = 33.0$, and $P << 0.001$, rejecting the null hypothesis. The difference in AIC_c scores is 30.9, and the Akaike weight for model 2 is effectively 1.0. All ways of comparing these two models give strong support for hypothesis 2. We can conclude that there is an evolutionary correlation between body mass and home range size in mammals. What this means in evolutionary terms is that, across mammals, evolutionary changes in body mass tend to positively covary with changes in home range.

Section 5.4b: Testing for character correlations using Bayesian model selection

We can also implement a Bayesian approach to testing for the correlated evolution of two characters. The simplest way to do this is just to use the standard algorithm for Bayesian MCMC to fit a correlated model to the two characters. We can modify the algorithm presented in chapter 2 as follows:

1. Sample a set of starting parameter values σ_x^2 , σ_y^2 , σ_{xy} , $\bar{z}_1(0)$, and $\bar{z}_2(0)$ from prior distributions. For this example, we can set our prior distribution as uniform between 0 and 1 for σ_x^2 and σ_y^2 , uniform from -1 to +1 for σ_{xy} , uniform from 1 to 9 for $\bar{z}_1(0)$ (`lnMass`), and -3 to 5 for $\bar{z}_2(0)$ (`lnHomerange`).
2. Given the current parameter values, select new proposed parameter values using the proposal density $Q(p'|p)$. Here, for all five parameter values, we will use a uniform proposal density with width 0.2, so that $Q(p'|p) \sim U(p - 0.1, p + 0.1)$.
3. Calculate three ratios:

- a. The prior odds ratio, R_{prior} . This is the ratio of the probability of drawing the parameter values p and p' from the prior. Since our priors are uniform, $R_{prior} = 1$.
- b. The proposal density ratio, $R_{proposal}$. This is the ratio of probability of proposals going from p to p' and the reverse. Our proposal density is symmetrical, so that $Q(p'|p) = Q(p|p')$ and $R_{proposal} = 1$.
- c. The likelihood ratio, $R_{likelihood}$. This is the ratio of probabilities of the data given the two different parameter values. We can calculate these probabilities from equation 5.6 above (eq. 5.12).

$$R_{likelihood} = \frac{L(p'|D)}{L(p|D)} = \frac{P(D|p')}{P(D|p)}$$

- Find R_{accept} , the product of the prior odds, proposal density ratio, and the likelihood ratio. In this case, both the prior odds and proposal density ratios are 1, so $R_{accept} = R_{likelihood}$.
- Draw a random number x from a uniform distribution between 0 and 1. If $x < R_{accept}$, accept the proposed value of all parameters; otherwise reject, and retain the current parameter values.
- Repeat steps 2-5 a large number of times.

We can then inspect the posterior distribution for the parameter is significantly greater than (or less than) zero. As an example, I ran this MCMC for 100,000 generations, discarding the first 10,000 generations as burn-in. I then sampled the posterior distribution every 100 generations, and obtained the following parameter estimates: $\hat{\sigma}_x^2 = 0.26$ (95% CI: 0.18 - 0.38), $\hat{\sigma}_y^2 = 0.10$ (95% CI: 0.06 - 0.15), and $\hat{\sigma}_{xy} = 0.11$ (95% CI: 0.06 - 0.17; see Figure 5.4). These results are comparable to our ML estimates. Furthermore, the 95% CI for $\hat{\sigma}_{xy}$ does not overlap with 0; in fact, none of the 901 posterior estimates of $\hat{\sigma}_{xy}$ are less than zero. Again, we can conclude with confidence that there is an evolutionary correlation between these two characters.

Section 5.5c: Testing for character correlations using traditional approaches (PIC, PGLS)

The approach outlined above, which tests for an evolutionary correlation among characters using model selection, is not typically applied

in the comparative biology literature. Instead, most tests of character correlation rely on phylogenetic regression using one of two methods: phylogenetic independent contrasts (PICs) and phylogenetic general least squares (PGLS). PGLS is actually mathematically identical to PICs in the simple case described here, and more flexible than PICs for other models and types of characters. Here I will review both PICs and PGLS and explain how they work and how they relate to the models described above.

Phylogenetic independent contrasts can be used to carry out a regression test for the relationship between two different characters. To do this, one calculates standardized PICs for trait x and trait y . One then uses standard linear regression forced through the origin to test for a relationship between these two sets of PICs. It is necessary to force the regression through the origin because the direction of subtraction of contrasts across any node in the tree is arbitrary; a reflection of all of the contrasts across both axes simultaneously should have no effect on the analyses³.

For mammal homorange and body mass, a PIC regression test shows a significant correlation between the two traits ($P << 0.0001$; Figure 5.5).

There is one drawback to PIC regression analysis, though – one does not recover an estimate of the intercept of the regression of y on x – that is, the value of y one would expect when $x = 0$. The easiest way to get this parameter estimate is to instead use Phylogenetic Generalized Least Squares (PGLS). PGLS uses the common statistical machinery of generalized least squares, and applies it to phylogenetic comparative data. In normal generalized least squares, one constructs a model of the relationship between y and x , as:

(eq. 5.13)

$$\mathbf{y} = \mathbf{X}_D \mathbf{b} + \epsilon$$

Here, \mathbf{y} is an $n \times 1$ vector of trait values and \mathbf{b} is a vector of unknown regression coefficients that must be estimated from the data. \mathbf{X}_D is a design matrix including the traits that one wishes to test for a correlation with y and – if the model includes an intercept – a column of 1s. To test for correlations, we use:

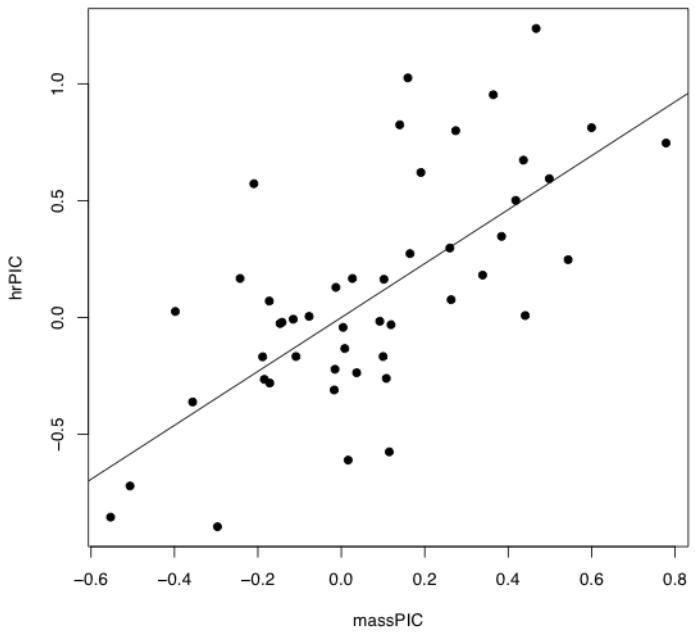

Figure 5.4. Regression based on independent contrasts. The regression line is forced through the origin.

(eq. 5.14)

$$\mathbf{X}_D = \begin{bmatrix} 1 & x_1 \\ 1 & x_2 \\ \dots & \dots \\ 1 & x_n \end{bmatrix}$$

In the case of one predictor and one response variable, \mathbf{b} is 2×1 and the resulting model can be used to test correlations between two characters. However, \mathbf{X}_D could also be multivariate, and can include more than one character that might be related to y . This allows us to carry out the equivalent of multiple regression in a phylogenetic context. Finally, ϵ are the residuals – the difference between the y -values predicted by the model and their actual values. In traditional regression, one assumes that the residuals are all normally distributed with the same variance. By contrast, with GLS, one assumes that the residuals might not be independent of each other; instead, they are multivariate normal with expected mean zero and some variance-covariance matrix Ω .

In the case of Brownian motion, we can model the residuals as having variances and covariances that follow the structure of the phylogenetic tree. In other words, we can substitute our phylogenetic variance-covariance matrix \mathbf{C} as the matrix Ω . We can then carry out standard GLS analyses to estimate model parameters:

(eq. 5.15)

$$\hat{\mathbf{b}} = (\mathbf{X}_D^\top \Omega^{-1} \mathbf{X}_D^\top)^{-1} \mathbf{X}_D^\top \Omega^{-1} \mathbf{y} = (\mathbf{X}_D^\top \mathbf{C}^{-1} \mathbf{X}_D^\top)^{-1} \mathbf{X}_D^\top \mathbf{C}^{-1} \mathbf{y}$$

The first term in $\hat{\mathbf{b}}$ is the phylogenetic mean $\bar{z}(0)$. The other term in $\hat{\mathbf{b}}$ will be an estimate for the slope of the relationship between y and x , the calculation of which statistically controls for the effect of phylogenetic relationships.

Applying PGLS to mammal body mass and home range results in an identical estimate of the slope and P-value as we obtain using independent contrasts (see Box 4.1). PGLS also returns an estimate of the intercept of this relationship, which cannot be obtained from the PICs.

Of course, another difference is that PICs and PGLS use regression, while the approach outlined above tests for a correlation. These two

types of statistical tests are different. Correlation tests for a relationship between x and y , while regression tries to find the best way to predict y from x . For correlation, it does not matter which variable we call x and which we call y . However, in regression we will get a different slope if we predict y given x instead of predicting x given y . The model that is assumed by phylogenetic regression models is also different from the model above, where we assumed that the two characters evolve under a correlated Brownian motion model. By contrast, PGLS (and, implicitly, PICs) assume that the deviations of each species from the regression line evolve under a Brownian motion model. We can imagine, for example, that species can freely slide along the regression line, but that evolving around that line can be captured by a normal Brownian model. Another way to think about a PGLS model is that we are treating x as a fixed property of species. The deviation of y from what is predicted by x is what evolves under a Brownian motion model. If this seems strange, that's because it is! There are other, more complex models for modeling the correlated evolution of two characters that make assumptions that are more evolutionarily realistic (e.g. Hansen 1997); we will return to this topic later in the book. At the same time, PGLS is a well-used method for evolutionary regression, and is undoubtedly useful despite its somewhat strange assumptions.

PGLS analysis, as described above, assumes that characters are evolving under a Brownian motion model. However, one can change the structure of the error variance-covariance matrix to reflect other models of evolution, such as Ornstein-Uhlenbeck. We return to this topic in a later chapter.

Section 5.6: Summary

There are at least four methods for testing for an evolutionary correlation between continuous characters: likelihood ratio test, AIC model selection, PICs, and PGLS. These four methods as presented all make the same assumptions about the data and, therefore, have quite similar statistical properties (even simulating under a multivariate Brownian motion model, which deviates from the model assumptions, both PICs and PGLS have appropriate Type I error rates and very similar power).

Any of these are good choices for testing for the presence of an evolutionary correlation in your data.

Section 5.7: Footnotes

- 1: We might also want to carry out linear regression, which is related to correlation analysis but distinct. We will show examples of phylogenetic regression at the end of this chapter.
- 2: Although the joint distribution of all species for a single trait is multivariate normal (see previous chapters), individual changes along a particular branch of a tree are univariate.
- 3: Another way to think about regression through the origin is to think of pairs of contrasts across any node in the tree as two-dimensional vectors. Calculating a vector correlation is equivalent to calculating a regression forced through the origin.

Chapter 6: Beyond Brownian Motion

Section 6.1: Introduction

Detailed studies of contemporary evolution have revealed a rich variety of processes that influence how traits evolve through time. Consider the famous studies of Darwin’s finches, *Geospiza*, in the Galapagos islands carried out by Peter and Rosemary Grant, among others (e.g. Grant and Grant 2011). These studies have documented the action of natural selection on traits from one generation to the next. One can see very clearly how changes in climate – especially the amount of rainfall – affect the availability of different types of seeds (Grant and Grant 2002). These changing resources in turn affect which individuals survive within the population. When natural selection acts on traits that can be inherited from parents to offspring, those traits evolve.

One can obtain a dataset of morphological traits, including measurements of body and beak size and shape, along with a phylogenetic tree for several species of Darwin’s finches. Imagine that you have the goal of analyzing the tempo and mode of morphological evolution across these species of finch. We can start by fitting a Brownian motion model to these data. However, a Brownian model (which, as we learned in Chapter 3, corresponds to a few simple scenarios of trait evolution) hardly seems realistic for a group of finches known to be under strong and predictable directional selection.

Brownian motion is very commonly in comparative biology: in fact, a large number of comparative methods that researchers use for continuous traits assumes that traits evolve under a Brownian motion model. The scope of other models beyond Brownian motion that we can use to model continuous trait data on trees is somewhat limited. However, more and more methods are being developed that break free of this limitation, moving the field beyond Brownian motion. In this chapter I will discuss these approaches and what they can tell us about evolution. I will also describe how moving beyond Brownian motion can point the way forward for statistical comparative methods.

In this chapter, I will consider four ways that comparative methods can move beyond simple Brownian motion models: by transforming the

variance-covariance matrix describing trait covariation among species, by incorporating variation in rates of evolution, by accounting for evolutionary constraints, and by modeling adaptive radiation and ecological opportunity. It should be apparent that the models listed here do not span the complete range of possibilities, and so my list is not meant to be comprehensive. Instead, I hope that readers will view these as examples, and that future researchers will add to this list and enrich the set of models that we can fit to comparative data.

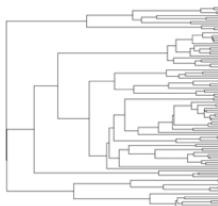

Section 6.2: Transforming the evolutionary variance-covariance matrix

In 1999, Mark Pagel introduced three statistical models that allow one to test whether data deviates from a constant-rate process evolving on a phylogenetic tree (Pagel 1999a,b)¹. Each of these three models is a statistical transformation of the elements of the phylogenetic variance-covariance matrix, \mathbf{C} , that we first encountered in Chapter 3. All three can also be thought of as a transformation of the branch lengths of the tree, which adds a more intuitive understanding of the statistical properties of the tree transformations (Figure 6.1). We can transform the tree and then simulate characters under a Brownian motion model on the transformed tree, generating very different patterns than if they had been simulated on the starting tree.

There are three Pagel tree transformations (lambda: λ , delta: δ , and kappa: κ). I will describe each of them along with common methods for fitting Pagel models under ML, AIC, and Bayesian frameworks. Pagel's three transformations can also be related to evolutionary processes, although those relationships are sometimes vague compared to approaches based on explicit evolutionary models rather than tree transformations (see below for more comments on this distinction).

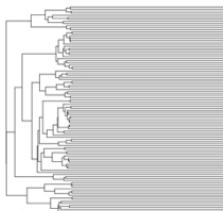

Perhaps the most commonly used Pagel tree transformation is λ . When using λ , one multiplies all off-diagonal elements in the phylogenetic variance-covariance matrix by the value of λ , restricted to values of $0 \leq \lambda \leq 1$. The diagonal elements remain unchanged. So, if the original matrix for r species is:

Starting tree

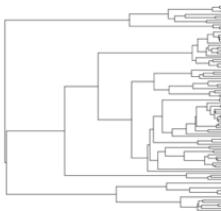

Tree Transformations

$\lambda = 0.3$

$\delta = 0.3$

$\kappa = 0.3$

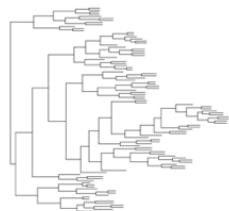

Figure 6.1. Branch length transformations effectively alter the relative rate of evolution on certain branches in the tree. If we make a branch longer, there is more “evolutionary time” for characters to change, and so we are effectively increasing the rate of evolution along that branch.

(Equation 6.1)

$$\mathbf{C}_o = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \dots & \sigma_{1r} \\ \sigma_{21} & \sigma_2^2 & \dots & \sigma_{2r} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{r1} & \sigma_{r2} & \dots & \sigma_r^2 \end{bmatrix}$$

Then the transformed matrix will be:

(Equation 6.2)

$$\mathbf{C}_\lambda = \begin{bmatrix} \sigma_1^2 & \lambda \cdot \sigma_{12} & \dots & \lambda \cdot \sigma_{1r} \\ \lambda \cdot \sigma_{21} & \sigma_2^2 & \dots & \lambda \cdot \sigma_{2r} \\ \vdots & \vdots & \ddots & \vdots \\ \lambda \cdot \sigma_{r1} & \lambda \cdot \sigma_{r2} & \dots & \sigma_r^2 \end{bmatrix}$$

In terms of branch length transformations, λ compresses internal branches while leaving the tip branches of the tree unaffected (Figure 6.1). λ can range from 1 (no transformation) to 0 (which results in a complete star phylogeny, with all tip branches equal in length and all internal branches of length 0). One can in principle use some values of λ greater than one on most variance-covariance matrices, although many values of $\lambda > 1$ result in matrices that are not valid variance-covariance matrices and/or do not correspond with any phylogenetic tree transformation. For this reason I recommend that λ be limited to values between 0 and 1.

λ is often used to measure the “phylogenetic signal” in comparative data. This makes intuitive sense, as λ scales the tree between a constant-rates model ($\lambda = 1$) to one where every species is statistically independent of every other species in the tree ($\lambda = 0$). Statistically, this can be very useful information. However, there is some danger in attributing a statistical result – either phylogenetic signal or not – to any particular biological process. For example, phylogenetic signal is sometimes called a “phylogenetic constraint.” But one way to obtain a high phylogenetic signal (λ near 1) is to evolve traits under a Brownian motion model, which involves completely unconstrained character evolution. Likewise, a lack of phylogenetic signal – which might be called “low phylogenetic constraint” – results from an OU model

with a high α parameter (see below), which is a model where trait evolution away from the optimal value is, in fact, highly constrained. Revell et al. (2008) show a broad range of circumstances that can lead to patterns of high or low phylogenetic signal, and caution against over-interpretation of results from analyses of phylogenetic signal, like Pagel's λ . Also worth noting is that statistical estimates of λ under a ML model tend to be clustered near 0 and 1 regardless of the true value, and AIC model selection can tend to prefer models with $\lambda \neq 0$ even when data is simulated under Brownian motion (Boettiger et al. 2012).

Pagel's δ is designed to capture variation in rates of evolution through time. Under the δ transformation, all elements of the phylogenetic variance-covariance matrix are raised to the power δ , assumed to be positive. So, if our original \mathbf{C} matrix is given above (equation 6.1), then the δ -transformed version will be:

(Equation 6.3)

$$\mathbf{C}_\delta = \begin{bmatrix} (\sigma_1^2)^\delta & (\sigma_{12})^\delta & \dots & (\sigma_{1r})^\delta \\ (\sigma_{21})^\delta & (\sigma_2^2)^\delta & \dots & (\sigma_{2r})^\delta \\ \vdots & \vdots & \ddots & \vdots \\ (\sigma_{r1})^\delta & (\sigma_{r2})^\delta & \dots & (\sigma_r^2)^\delta \end{bmatrix}$$

Since these elements represent the heights of nodes in the phylogenetic tree, then δ can also be viewed as a transformation of phylogenetic node heights. When δ is one, the tree is unchanged and one still has a constant-rate Brownian motion process; when δ is less than 1, node heights are reduced, but deeper branches in the tree are reduced less than shallower branches (Figure 6.1). This effectively represents a model where the rate of evolution slows through time. By contrast, $\delta > 1$ stretches the shallower branches in the tree more than the deep branches, mimicking a model where the rate of evolution speeds up through time. There is a close connection between the δ model, the ACDC model (Blomberg et al. 2003), and Harmon et al.'s (2010) early burst model [see also Uyeda and Harmon (2014), especially the appendix].

Finally, the κ transformation is sometimes used to capture patterns of "speciational" change in trees. In the κ model, one raises all of the

branch lengths in the tree by the power κ (we require that $\kappa \geq 0$). This has a complicated effect on the phylogenetic variance-covariance matrix, as the effect that this transformation has on each covariance element depends on both the value of κ and the number of branches that extend from the root of the tree to the most recent common ancestor of each pair of species. So, if our original \mathbf{C} matrix is given by equation 6.1, the transformed version will be:

(Equation 6.4)

$$\mathbf{C}_\kappa = \begin{pmatrix} b_{1,1}^k + b_{1,2}^k + \dots + b_{1,d_1}^k & b_{1-2,1}^k + b_{1-2,2}^k + \dots + b_{1-2,d_{1-2}}^k & \dots & b_{1-r,1}^k + b_{1-r,2}^k + \dots + b_{1-r,d_{1-r}}^k \\ b_{2-1,1}^k + b_{2-1,2}^k + \dots + b_{2-1,d_{1-2}}^k & b_{2,1}^k + b_{2,2}^k + \dots + b_{2,d_2}^k & \dots & b_{2-r,1}^k + b_{2-r,2}^k + \dots + b_{2-r,d_{2-r}}^k \\ \vdots & \vdots & \ddots & \vdots \\ b_{r-1,1}^k + b_{r-1,2}^k + \dots + b_{r-1,d_{1-r}}^k & b_{r-2,1}^k + b_{r-2,2}^k + \dots + b_{r-2,d_{1-2}}^k & \dots & b_{r,1}^k + b_{r,2}^k + \dots + b_{r,d_r}^k \end{pmatrix}$$

where $b_{x,y}$ is the branch length of the branch that is the most recent common ancestor of taxa x and y , while $d_{x,y}$ is the total number of branches that one encounters traversing the path from the root to the most recent common ancestor of the species pair specified by x, y (or to the tip x if just one taxon is specified). Needless to say, this transformation is easier to understand as a transformation of the tree branches themselves rather than of the associated variance-covariance matrix.

When the κ parameter is one, the tree is unchanged and one still has a constant-rate Brownian motion process; when $\kappa = 0$, all branch lengths are one. κ values in between these two extremes represent intermediates (Figure 6.1). κ is often interpreted in terms of a model where character change is more or less concentrated at speciation events. For this interpretation to be valid, we have to assume that the phylogenetic tree, as given, includes all (or even most) of the speciation events in the history of the clade. The problem with this assumption is that speciation events are almost certainly missing due to sampling: perhaps some living species from the clade have not been sampled, or species that are part of the clade have gone extinct before the present day and are thus not sampled. There are much better ways of estimating speciation models that can account for these issues in sampling (e.g. Bokma 2008; Goldberg and Igić 2012); these newer methods should be preferred over Pagel's κ for testing for a speciation pattern in trait data.

There are two main ways to assess the fit of the three Pagel-style models to data. First, one can use ML to estimate parameters and likelihood ratio tests (or AIC_c scores) to compare the fit of various models. Each represents a three parameter model: one additional parameter added to the two parameters already needed to describe single-rate Brownian motion. As mentioned above, simulation studies suggest that this can sometimes lead to overconfidence, at least for the λ model. Sometimes researchers will compare the fit of a particular model (e.g. λ) with models where that parameter is fixed at its two extreme values (0 or 1; this is not possible with δ). Second, one can use Bayesian methods to estimate posterior distributions of parameter values, then inspect those distributions to see if they overlap with values of interest (say, 0 or 1).

We can apply these three Pagel models to the mammal body size data discussed in chapter 5, comparing the AIC_c scores for Brownian motion to that from the three transformations. We obtain the following results:

Model	Parameter estimates	lnL	AIC_c
Brownian motion	$\sigma^2 = 0.088, \theta = 4.64$	-78.0	160.4
lambda	$\sigma^2 = 0.085, \theta = 4.64, \lambda = 1.0$	-78.0	162.6
delta	$\sigma^2 = 0.063, \theta = 4.60, \delta = 1.5$	-77.7	162.0
kappa	$\sigma^2 = 0.170, \theta = 4.64, \kappa = 0.66$	-77.3	161.1

Note that Brownian motion is the preferred model with the lowest AIC_c score, but also that all four AIC_c scores are within 3 units – meaning that we cannot easily distinguish among them using our mammal data.

Section 6.3: Variation in rates of trait evolution across clades

One assumption of Brownian motion is that the rate of change (σ^2) is constant, both through time and across lineages. However, some of the most interesting hypotheses in evolution relate to differences in the rates of character change across clades. For example, key innovations are evolutionary events that open up new areas of niche space

to evolving clades (Hunter 1998; reviewed in Alfaro 2013). This new niche space is an ecological opportunity that can then be filled by newly evolved species (Yoder et al. 2010). If this were happening in a clade, we might expect that rates of trait evolution would be elevated following the acquisition of the key innovation (Yoder et al. 2010).

There are several methods that one can use to test for differences in the rate of evolution across clades. First, one can compare the magnitude of independent contrasts across clades; second, one can use model comparison approaches to compare the fit of single- and multiple-rate models to data on trees; and third, one can use a Bayesian approach combined with reversible-jump machinery to try to find the places on the tree where rate shifts have occurred. I will explain each of these methods in turn.

Section 6.3a: Rate tests using phylogenetic independent contrasts

One of the earliest methods developed to compare rates across clades is to compare the magnitude of independent contrasts calculated in each clade (e.g. Garland 1992). To do this, one first calculates standardized independent contrasts, separating those contrasts that are calculated within each clade of interest. As we noted in Chapter 5, these contrasts have arbitrary sign (positive or negative) but if they are squared, represent independent estimates of the Brownian motion rate parameter (σ^2). Basically, when rates of evolution are high, we should see large independent contrasts in that part of the tree (Garland 1992).

In his original description of this approach, Garland (1992) proposed using a statistical test to compare the absolute value of contrasts between clades (or between a single clade and the rest of the phylogenetic tree). In particular, Garland (1992) suggests using a t-test, as long as the absolute value of independent contrasts are approximately normally distributed. However, under a Brownian motion model, the contrasts themselves – but not the absolute values of the contrasts – should be approximately normal, so it is quite likely that absolute values of contrasts will strongly violate the assumptions of a t-test.

In fact, if we try this test on mammal body size, contrasting the two

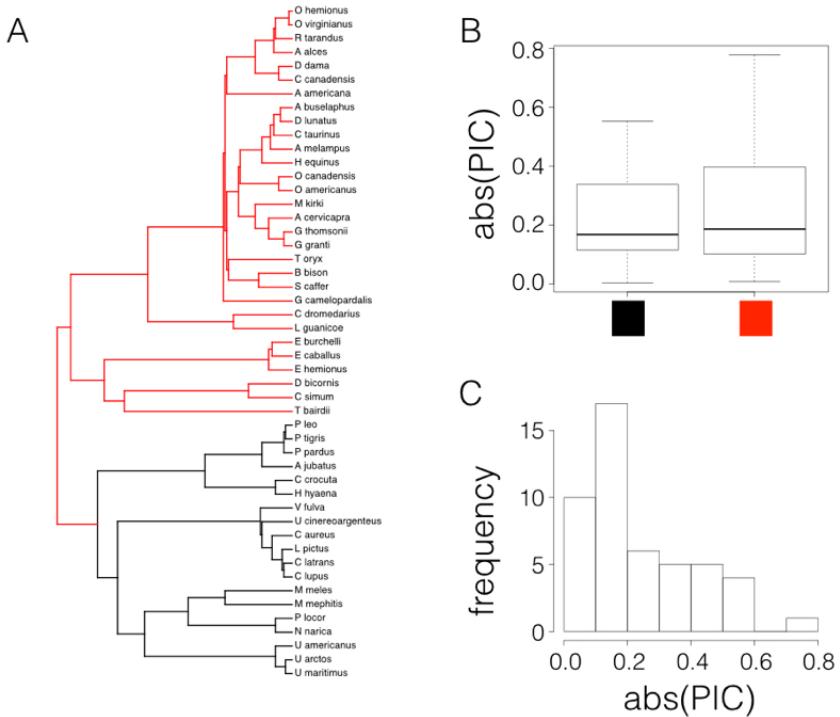

Figure 6.2. Rate tests comparing carnivores (black) with other mammals (red; Panel A). Box-plots show only a slight difference in the absolute value of independent contrasts for the two clades, and the distribution of absolute values of contrasts is strongly skewed.

major clades in the tree (carnivores versus non-carnivores, Figure 6.2A), there looks to be a small difference in the absolute value of contrasts (Figure 6.2B). A t-test is not significant (Welch two-sample t-test $P = 0.42$), but we also can see that the distribution of PIC absolute values is strongly skewed (Figure 6.2C).

There are other simple options that might work better in general. For example, one could also compare the magnitudes of the squared contrasts, although these are also not expected to follow a normal distribution. Alternatively, we can again follow Garland's (1992) suggestion and use a Mann-Whitney U-test, the nonparametric equivalent of a t-test, on the absolute values of the contrasts. Since Mann-Whitney U tests use ranks instead of values, this approach will not be sensitive to the fact that the absolute values of contrasts are not normal. If the P-value is significant for this test then we have evidence that the rate of evolution is greater in one part of the tree than another.

In the case of mammals, a Mann-Whitney U test also shows no significant differences in rates of evolution between carnivores and other mammals ($W = 251$, $P = 0.70$).

Section 6.3b: Rate tests using maximum likelihood and AIC

One can also carry out rate comparisons using a model-selection framework (O'Meara et al. 2006b, Thomas et al. (2006)). To do this, we can fit single- and multiple-rate Brownian motion models to a phylogenetic tree, then compare them using a model selection method like AIC_c . For example, in the example above, we tested whether or not one subclade in the mammal tree (carnivores) has a very different rate of body size evolution than the rest of the clade. We can use an ML-based model selection method to compare the fit of a single-rate model to a model where the evolutionary rate in carnivores is different from the rest of the clade, and use this test evaluate the support for that hypothesis.

This test requires the likelihood for a multi-rate Brownian motion model on a phylogenetic tree. We can derive such an equation following the approach presented in Chapter 4. Recall that the likelihood equations for (constant-rate) Brownian motion use a phylogenetic variance-covariance matrix, \mathbf{C} , that is based on the branch lengths and topology

of the tree. For single-rate Brownian motion, the elements in \mathbf{C} are derived from the branch lengths in the tree. Traits are drawn from a multivariate normal distribution with variance-covariance matrix:

(Equation 6.5)

$$\mathbf{V}_{H_1} = \sigma^2 \mathbf{C}_{tree}$$

One simple way to fit a multi-rate Brownian motion model is to construct separate \mathbf{C} matrices, one for each rate category in the tree. For example, imagine that most of a clade evolves under a Brownian motion model with rate σ_1^2 , but one clade in the tree evolves at a different (higher or lower) rate, σ_2^2 . One can construct two \mathbf{C} matrices: the first matrix, \mathbf{C}_1 , includes branches that evolve under rate σ_1^2 , while the second, \mathbf{C}_2 , includes only branches that evolve under rate σ_2^2 . Since all branches in the tree are included in one of these two categories, it will be true that $\mathbf{C}_{tree} = \mathbf{C}_1 + \mathbf{C}_2$. For any particular values of these two rates, traits are drawn from a multivariate normal distribution with variance-covariance matrix:

(Equation 6.6)

$$\mathbf{V}_{H_2} = \sigma_1^2 \mathbf{C}_1 + \sigma_2^2 \mathbf{C}_2$$

We can now treat this as a model comparison-problem, contrasting H_1 : traits on the tree evolved under a constant-rate Brownian motion model, with H_2 : traits on the tree evolved under a multi-rate Brownian motion model. Note that H_1 is a special case of H_2 when $\sigma_1^2 = \sigma_2^2$; that is, these two models are nested and can be compared using a likelihood ratio test. Of course, one can also compare the two models using AIC_c .

For the mammal body size example, you might recall our ML single-rate Brownian motion model ($\sigma^2 = 0.088$, $\bar{z}(0) = 4.64$, $\ln L = -78.0$, $AIC_c = 160.4$). We can compare that to the fit of a model where carnivores get their own rate parameter (σ_c^2) that might differ from that of the rest of the tree (σ_o^2). Fitting that model, we find the following maximum likelihood parameter estimates: $\hat{\sigma}_c^2 = 0.068$, $\hat{\sigma}_o^2 = 0.01$, $\hat{\bar{z}}(0) = 4.51$). Carnivores do appear to be evolving more rapidly. However, the fit of this model is not substantially better than the single-rate Brownian motion ($\ln L = -77.6$, $AIC_c = 162.3$).

There is one complication, which is how to deal with the actual branch along which the rate shift is thought to have occurred. O'Meara et al. (2006b) describe "censored" and "noncensored" versions of their test, which differ in whether or not branches where rate shifts actually occur are included in the calculation. In the censored version of the test, O'Meara et al. (2006b) omit the branch where we think a shift occurred, while in the noncensored version O'Meara et al. (2006b) include that branch in one of the two rate categories (this is what I did in the example above, adding the stem branch of carnivores in the "non-carnivore" category). One could also specify where, exactly, the rate shift occurred along the branch in question, placing part of the branch in each of the two rate categories as appropriate. However, since we typically have little information about what happened on particular branches in a phylogenetic tree, results from these two approaches are not very different – unless, as stated by O'Meara et al. (2006b), unusual evolutionary processes have occurred on the branch in question.

A similar approach was described by Thomas et al. (2006) but considers differences across clades to include changes in any of the two parameters of a Brownian motion model (σ^2 , $\bar{z}(0)$, or both). Remember that $\bar{z}(0)$ is the expected mean of species within a clade under a Brownian motion, but also represents the starting value of the trait at time zero. Allowing $\bar{z}(0)$ to vary across clades effectively allows different clades to have different "starting points" in phenotype space. In the case of comparing a monophyletic subclade to the rest of a tree, Thomas et al.'s (2006) approach is equivalent to the "censored" test described above. However, one drawback to both the Thomas et al. (2006) approach and the "censored" test is that, because clades each have their own mean, we no longer can tie the model that we fit using likelihood to any particular evolutionary process. Mathematically, changing $\bar{z}(0)$ in a subclade postulates that the trait value changed somehow along the branch leading to that clade, but we do not specify the way that the trait changed – the change could have been gradual or instantaneous, and no amount or pattern of change is more or less likely than anything else. Of course, one can describe evolutionary scenarios that might act like this process - but we begin to lose any potential tie to explicit evolutionary processes.

Section 6.3c: Rate tests using Bayesian MCMC

It is also possible to carry out this test in a Bayesian MCMC framework. The simplest way to do that would be to fit model H2 above, that traits on the tree evolved under a multi-rate Brownian motion model, in a Bayesian framework. We can then specify prior distributions and sample the three model parameters ($\bar{z}(0)$, σ_1^2 , and σ_2^2) through our MCMC. At the end of our analysis, we will have posterior distributions for the three model parameters. We can test whether rates differ among clades by calculating a posterior distribution for the composite parameter $\sigma_{diff}^2 = \sigma_1^2 - \sigma_2^2$. The proportion of the posterior distribution for σ_{diff}^2 that is positive or negative gives the posterior probability that σ_1^2 is greater or less than σ_2^2 , respectively.

Perhaps, though, researchers are unsure of where, exactly, the rate shift might have occurred, and want to incorporate some uncertainty in their analysis. In some cases, rate shifts are thought to be associated with some other discrete character, such as living on land (state 0) or in the water (1). In such cases, one way to proceed is to use stochastic character mapping (see Chapter 8) to map state changes for the discrete character on the tree, and then run an analysis where rates of evolution of the continuous character of interest depend on the mapping of our discrete states. This protocol is described most fully by Revell (2013), who also points out that rate estimates are biased to be more similar when the discrete character evolves quickly.

It is even possible to explore variation in Brownian rates without invoking particular *a priori* hypotheses about where the rates might change along branches in a tree. These methods rely on reversible-jump MCMC, a Bayesian statistical technique that allows one to consider a large number of models, all with different numbers of parameters, in a single Bayesian analysis. In this case, we consider models where each branch in the tree can potentially have its own Brownian rate parameter. By constraining sets of these rate parameters to be equal to one another, we can specify a huge number of models for rate variation across trees. The reversible-jump machinery, which is beyond the scope of this book, allows us to generate a posterior distribution that spans this large set of models where rates vary along branches in a phylogenetic tree (see Eastman et al. 2011 for details).

Section 6.4: Non-Brownian evolution under stabilizing selection

We can also consider the case where a trait evolves under the influence of stabilizing selection. Assume that a trait has some optimal value, and that when the population mean differs from the optimum the population will experience selection towards the optimum (Figure 6.3). As I will show below, when traits evolve under stabilizing selection with a constant optimum, the pattern of traits through time can be described under an Ornstein-Uhlenbeck (OU) model. It is worth mentioning, though, that this is only one (of many!) models that follow an OU process over long time scales. In other words, even though this model can be described by OU, we cannot make inferences the other direction and claim that OU means that our population is under constant stabilizing selection. In fact, we will see later that we can almost always rule this simple version of the OU model out over long time scales by looking at the actual parameter values of the model compared to what we know about species' population sizes and trait heritabilities.

Figure 6.3. Plot of species trait (x axis) versus fitness (y axis) showing a hypothetical landscape that would produce stabilizing selection.

We can follow the modeling approach from chapter 3 to derive the expected distribution of species' traits on a tree under stabilizing selection. The derivation is a bit long and complicated, so I have moved it to an appendix of this chapter. For now, all you need to know is that

we can write down the likelihood of an OU model on a phylogenetic tree (see equation 6.58-6.60, below).

We can fit an OU model to data in a similar way to how we fit BM models in the previous chapters. For any given parameters (\bar{z}_0 , σ^2 , α , and θ) and a phylogenetic tree with branch lengths, one can calculate an expected vector of species means and a species variance-covariance matrix. One then uses the likelihood equation for a multivariate normal distribution to calculate the likelihood of this model. This likelihood can then be used for parameter estimation in either a ML or a Bayesian framework.

We can illustrate how this works by fitting an OU model to the mammal body size data that we have been discussing. Using ML, we obtain parameter estimates $\hat{\bar{z}}_0 = 4.60$, $\hat{\sigma}^2 = 0.10$, $\hat{\alpha} = 0.0082$, and $\hat{\theta} = 4.60$. This model has a $\ln L$ of -77.6, a little higher than BM, but an AIC_c score of 161.2, worse than BM. We still prefer Brownian motion for these data. Over many datasets, though, OU models fit better than Brownian motion (see Harmon et al. 2010; Pennell and Harmon 2013).

Section 6.6: Early burst models

Adaptive radiations are a slippery idea. Many definitions have been proposed, some of which contradict one another (reviewed in Yoder et al. 2010). Despite some core disagreement about the concept of adaptive radiations, many discussions of the phenomenon center around the idea of “ecological opportunity.” Perhaps adaptive radiations begin when lineages gain access to some previously unexploited area of niche space. These lineages begin diversifying rapidly, forming many and varied new species. At some point, though, one would expect that the ecological opportunity would be “used up,” so that species would go back to diversifying at their normal, background rates (Yoder et al. 2010). These ideas connect to Simpson’s description of evolution in adaptive zones. According to Simpson (1945), species enter new adaptive zones in one of three ways: dispersal to a new area, extinction of competitors, or the evolution of a new trait or set of traits that allow them to interact with the environment in a new way.

One idea, then, is that we could detect the presence of adaptive radiations by looking for bursts of trait evolution deep in the tree. If we can identify clades, like Darwin’s finches, for example, that might be adaptive radiations, we should be able to uncover this “early burst” pattern of trait evolution.

The simplest way to model an early burst of evolution in a continuous trait is to use a time-varying Brownian motion model. Imagine that species in a clade evolved under a Brownian motion model, but one where the Brownian rate parameter (σ^2) slowed through time. In particular, we can follow Harmon et al. (2010) and define the rate parameter as a function of time, as:

(Equation 6.7)

$$\sigma^2(t) = \sigma_0^2 e^{bt}$$

We describe the rate of decay of the rate using the parameter b , which must be negative to fit our idea of adaptive radiations. The rate of evolution will slow through time, and will decay more quickly if the absolute value of b is large.

This model also generates a multivariate normal distribution of tip values. Harmon et al. (2010) followed Blomberg’s “ACDC” model (2003) to write equations for the means and variances of tips on a tree under this model, which are:

(Equations 6.8-10)

$$\begin{aligned}\mu_i(t) &= \bar{z}_0 \\ V_i(t) &= \sigma_0^2 \frac{e^{bt_i} - 1}{b} V_{ij}(t) = \sigma_0^2 \frac{e^{bs_{ij}} - 1}{b}\end{aligned}$$

Again, we can generate a vector of means and a variance-covariance matrix for this model given parameter values (\bar{z}_0 , σ^2 , and b) and a phylogenetic tree. We can then use the multivariate normal probability distribution function to calculate a likelihood, which we can then use in a ML or Bayesian statistical framework.

For mammal body size, the early burst model does not explain patterns of body size evolution, at least for the data considered here ($\hat{\bar{z}}_0 = 4.64$, $\hat{\sigma}^2 = 0.088$, $\hat{b} = -0.000001$, $\ln L = -78.0$, $AIC_c = 162.6$).

Section 6.7: Peak shift models

A second model considered by Hansen and Martins (1996) describes the circumstance where traits change in a punctuated manner. One can imagine a scenario where species evolve on an adaptive landscape with many peaks; usually, populations stay on a single peak and phenotypes do not change, but occasionally a population will transition from one peak to another. We can either assume that these changes occur at random times, defining an average interval between peak shifts, or we can associate shifts with other traits that we map on the phylogenetic tree (for example, major geographic dispersal or vicariance events, or the evolution of certain traits).

We have developed peak shift models by integrating OU models and reversible-jump MCMC (Uyeda and Harmon 2014). The mathematics of this model are beyond the scope of this book, but follow closely from the description of the multi-rate Brownian motion model described in the section “variation in rates of trait evolution across clades,” above. In this case, when we change model parameters, we move among OU regimes, and can alter the OU model parameters σ^2 or α . The approach can be used to either identify parts of the tree that are evolving in separate regimes or to test particular hypotheses about the drivers of evolution.

Section 6.8: Summary

In this chapter, I have described a few models that represent alternatives to Brownian motion, which is still the dominant model of trait evolution used in the literature. These examples really represent the beginnings of a whole set of models that one might fit to biological data. The best applications of this type of approach, I think, are in testing particular biologically motivated hypotheses using comparative data.

Section 6.9: Footnotes

1: Pagel's original models were initially focused on discrete characters, but - as he later pointed out - apply equally well to continuous characters.

Section 6.10: Appendix: Deriving an OU model under stabilizing selection

We can first consider the evolution of the trait on the “stem” branch, before the divergence of species A and B. We model stabilizing selection with a single optimal trait value, located at θ . An example of such a surface is plotted as Figure 6.3. We can describe fitness of an individual with phenotype z as:

(Equation 6.11)

$$W = e^{-\gamma(z-\theta)^2}$$

We have introduced a new variable, γ , which captures the curvature of the selection surface. To simplify the calculations, we will assume that stabilizing selection is weak, so that γ is small.

We can use a Taylor expansion of this function to approximate equation 6.7 using a polynomial. Our assumption that γ is small means that we can ignore terms of order higher than γ^2 :

(Equation 6.12)

$$W = 1 - \gamma(z - \theta)^2$$

This makes good sense, since a quadratic equation is a good approximation of the shape of a normal distribution near its peak. The mean fitness in the population is then:

(Equation 6.13)

$$\begin{aligned}\bar{W} &= E[W] = E[1 - \gamma(z - \theta)^2] \\ &= E[1 - \gamma(z^2 - 2z\theta + \theta^2)] \\ &= 1 - \gamma(E[z^2] - E[2z\theta] + E[\theta^2]) \\ &= 1 - \gamma(\bar{z}^2 - V_z - 2\bar{z}\theta + \theta^2)\end{aligned}$$

We can find the rate of change of fitness with respect to changes in the trait mean by taking the derivative of (6.9) with respect to \bar{z} :

(Equation 6.14)

$$\frac{\partial \bar{W}}{\partial \bar{z}} = -2\gamma\bar{z} + 2\gamma\theta = 2\gamma(\theta - \bar{z})$$

We can now use Lande's (1976) equation for the dynamics of the population mean through time for a trait under selection:

(Equation 6.15)

$$\Delta\bar{z} = \frac{G}{\bar{W}} \frac{\partial \bar{W}}{\partial \bar{z}}$$

Substituting equations 6.9 and 6.10 into equation 6.11, we have:

(Equation 6.16)

$$\Delta\bar{z} = \frac{G}{\bar{W}} \frac{\partial \bar{W}}{\partial \bar{z}} = \frac{G}{1 - \gamma(\bar{z}^2 - V_z - 2\bar{z}\theta + \theta^2)} 2\gamma(\theta - \bar{z})$$

Then, simplifying further with another Taylor expansion, we obtain:

(Equation 6.17)

$$\bar{z}' = \bar{z} + 2G\gamma(\theta - \bar{z}) + \delta$$

Here, \bar{z} is the species' trait value in the previous generation and \bar{z}' in the next, while G is the additive genetic variance in the population, γ the curvature of the selection surface, θ the optimal trait value, and δ a random component capturing the effect of genetic drift. We can find the expected mean of the trait over time by taking the expectation of this equation:

(Equation 6.18)

$$E[\bar{z}'] = \mu'_z = \mu_z + 2G\gamma(\theta - \mu_z)$$

We can then solve this differential equations given the starting condition $\mu_z(0) = \bar{z}(0)$. Doing so, we obtain:

(Equation 6.19)

$$\mu_z(t) = \theta + e^{-2Gt\gamma}(\bar{z}(0) - \theta)$$

We can take a similar approach to calculate the expected variance of trait values across replicates. We use a standard expression for variance:

(Equations 6.20-22)

$$\begin{aligned} V'_z &= E[\bar{z}'^2] + E[\bar{z}']^2 \\ V'_z &= E[(\bar{z} + 2G\gamma(\theta - \bar{z}) + \delta)^2] - E[\bar{z} + 2G\gamma(\theta - \bar{z}) + \delta]^2 \\ V'_z &= G/n + (1 - 2G\gamma)^2 V_z \end{aligned}$$

If we assume that stabilizing selection is weak, we can simplify the above expression using a Taylor series expansion:

(Equation 6.23)

$$V'_z = G/n + (1 - 4G\gamma)V_z$$

We can then solve this differential equation with starting point $V_z(0) = 0$:

(Equation 6.24)

$$V_z(t) = \frac{e^{-4Gt\gamma} - 1}{4n\gamma}$$

Equations 6.15 and 6.20 are equivalent to a standard stochastic model for constrained random walks called an Ornstein-Uhlenbeck process. Typical Ornstein-Uhlenbeck processes have four parameters: the starting value ($\bar{z}(0)$), the optimum (θ), the drift parameter (σ^2), and a parameter describing the strength of constraints (α). In our parameterization, $\bar{z}(0)$ and θ are as given, $\alpha = 2G$, and $\sigma^2 = G/n$.

We now need to know how OU models behave when considered along the branches of a phylogenetic tree. In the simplest case, we can describe the joint distribution of two species, A and B, descended from a common ancestor, z. Using equation 6.17, expressions for trait values of species A and B are:

(Equations 6.25-26)

$$\begin{aligned}\bar{a}' &= \bar{a} + 2G\gamma(\theta - \bar{a}) + \delta \\ \bar{b}' &= \bar{b} + 2G\gamma(\theta - \bar{b}) + \delta\end{aligned}$$

Expected values of these two equations give equations for the means, using equation 6.19:

(Equations 6.27-28)

$$\begin{aligned}\mu'_a &= \mu_a + 2G\gamma(\theta - \mu_a) \\ \mu'_b &= \mu_b + 2G\gamma(\theta - \mu_b)\end{aligned}$$

We can solve this system of differential equations, given starting conditions $\mu_a(0) = \bar{a}_0$ and $\mu_b(0) = \bar{b}_0$:

(Equations 6.29-30)

$$\begin{aligned}\mu'_a(t) &= \theta + e^{-2Gt\gamma}(\bar{a}_0 - \theta) \\ \mu'_b(t) &= \theta + e^{-2Gt\gamma}(\bar{b}_0 - \theta)\end{aligned}$$

However, we can also note that the starting value for both a and b is the same as the ending value for species z on the root branch of the tree. If we denote the length of that branch as t_1 then:

(Equation 6.31)

$$E[\bar{a}_0] = E[\bar{b}_0] = E[\bar{z}(t_1)] = e^{-2Gt_1\gamma}(\bar{z}_0 - \theta)$$

Substituting this into equations (6.25-26):

(Equations 6.32-33)

$$\begin{aligned}\mu'_a(t) &= \theta + e^{-2G\gamma(t_1+t)}(\bar{z}_0 - \theta) \\ \mu'_b(t) &= \theta + e^{-2G\gamma(t_1+t)}(\bar{z}_0 - \theta)\end{aligned}$$

Equations

We can calculate the expected variance across replicates of species A and B, as above:

(Equations 6.34-36)

$$\begin{aligned} V'_a &= E[\bar{a}'^2] + E[\bar{a}']^2 \\ V'_a &= E[(\bar{a} + 2G\gamma(\theta - \bar{a}) + \delta)^2] + E[\bar{a} + 2G\gamma(\theta - \bar{a}) + \delta]^2 \\ V'_a &= G/n + (1 - 2G\gamma)^2 V_a \end{aligned}$$

Similarly,

(Equations 6.37-38)

$$\begin{aligned} V'_b &= E[\bar{b}'^2] + E[\bar{b}']^2 \\ V'_b &= G/n + (1 - 2G\gamma)^2 V_b \end{aligned}$$

Again we can assume that stabilizing selection is weak, and simplify these expressions using a Taylor series expansion:

(Equations 6.39-40)

$$\begin{aligned} V'_a &= G/n + (1 - 4G\gamma)V_a \\ V'_b &= G/n + (1 - 4G\gamma)V_b \end{aligned}$$

We have a third term to consider, the covariance between species A and B due to their shared ancestry. We can use a standard expression for covariance to set up a third differential equation:

(Equations 6.41-43)

$$\begin{aligned} V'_{ab} &= E[\bar{a}'\bar{b}'] + E[\bar{a}']E[\bar{b}'] \\ V'_{ab} &= E[(\bar{a} + 2G\gamma(\theta - \bar{a}) + \delta)(\bar{b} + 2G\gamma(\theta - \bar{b}) + \delta)] + E[\bar{a} + 2G\gamma(\theta - \bar{a}) + \delta]E[\bar{a} + 2G\gamma(\theta - \bar{a}) + \delta] \\ V'_{ab} &= V_{ab}(1 - 2G\gamma)^2 \end{aligned}$$

We again use a Taylor series expansion to simplify:

(Equations 6.44)

$$V'_{ab} = -4V_{ab}G\gamma$$

Note that under this model the covariance between A and B decreases through time following their divergence from a common ancestor.

We now have a system of three differential equations. Setting initial conditions $V_a(0) = V_{a0}$, $V_b(0) = V_{b0}$, and $V_{ab}(0) = V_{ab0}$, we solve to obtain:

(Equations 6.45-47)

$$\begin{aligned}V_a(t) &= \frac{1-e^{-4G\gamma t}}{4n\gamma} + V_{a0} \\V_b(t) &= \frac{1-e^{-4G\gamma t}}{4n\gamma} + V_{b0} \\V_{ab}(t) &= V_{ab0}e^{-4G\gamma t}\end{aligned}$$

We can further specify the starting conditions by noting that both the variance of A and B and their covariance have an initial value given by the variance of z at time t_1 :

(Equations 6.48)

$$V_{a0} = V_{ab0} = V_{b0} = V_z(t_1) = \frac{e^{-4G\gamma t_1} - 1}{4n\gamma}$$

Substituting 6.44 into 6.41-43, we obtain:

(Equations 6.49-51)

$$\begin{aligned}V_a(t) &= \frac{e^{-4G\gamma(t_1+t)} - 1}{4n\gamma} \\V_b(t) &= \frac{e^{-4G\gamma(t_1+t)} - 1}{4n\gamma} \\V_{ab}(t) &= \frac{e^{-4G\gamma t} - e^{-4G\gamma(t_1+t)}}{4n\gamma}\end{aligned}$$

Under this model, the trait values follow a multivariate normal distribution; one can calculate that all of the other moments of this distribution are zero. Thus, the set of means, variances, and covariances completely describes the distribution of A and B. Also, as γ goes to zero, the selection surface becomes flatter and flatter. Thus at the limit as γ approaches 0, these equations are equal to those for Brownian motion (see chapter 4).

This quantitative genetic formulation – which follows Lande (1976) – is different from the typical parameterization of the OU model for comparative methods. We can obtain the “normal” OU equations by substituting $\alpha = 2G\gamma$ and $\sigma^2 = G/n$:

(Equations 6.52-54)

$$\begin{aligned} V_a(t) &= \frac{\sigma^2}{2\alpha}(e^{-2\alpha(t_1+t)} - 1) \\ V_b(t) &= \frac{\sigma^2}{2\alpha}(e^{-2\alpha(t_1+t)} - 1) \\ V_{ab}(t) &= \frac{\sigma^2}{2\alpha}e^{-2\alpha t}(1 - e^{-2\alpha t_1}) \end{aligned}$$

These equations are mathematically equivalent to the equations in Butler et al. (2004) applied to a phylogenetic tree with two species.

We can easily generalize this approach to a full phylogenetic tree with n taxa. In that case, the n species trait values will all be drawn from a multivariate normal distribution. The mean trait value for species i is then:

(Equation 6.55)

$$\mu_i(t) = \theta + e^{-2G\gamma T_i}(\bar{z}_0 - \theta)$$

Here T_i represents the total branch length separating that species from the root of the tree. The variance of species i is:

(Equation 6.56)

$$V_i(t) = \frac{e^{-4G\gamma T_i} - 1}{4n\gamma}$$

Finally, the covariance between species i and j is:

(Equation 6.57)

$$V_{ij}(t) = \frac{e^{-4G\gamma(T_i-s_{ij})} - e^{-4G\gamma T_i}}{4n\gamma}$$

Note that the above equation is only true when $T_i = T_j$ – which is only true for all i and j if the tree is ultrametric. We can substitute the normal OU parameters, α and σ^2 , into these equations:

(Equations 6.58-60)

$$\begin{aligned} \mu_i(t) &= \theta + e^{-\alpha T_i}(\bar{z}_0 - \theta) \\ V_i(t) &= \frac{\sigma^2}{2\alpha}e^{-2\alpha T_i} - 1 \\ V_{ij}(t) &= \frac{\sigma^2}{2\alpha}(e^{-2\alpha(T_i-s_{ij})} - e^{-2\alpha T_i}) \end{aligned}$$

Chapter 7: Models of discrete character evolution

Section 7.1: Limblessness as a discrete trait

Squamates, the clade that includes all living species of lizards, are well known for their diversity. From the gigantic Komodo dragon of Indonesia (Figure 7.1A, *Varanus komodoensis*) to tiny leaf chameleons of Madagascar (Figure 7.1B, *Brookesia*), squamates span an impressive range of form and ecological niche use (Vitt et al. 2003; Pianka et al. 2017). Even the snakes (Figure 7.1C and D), extraordinarily diverse in their own right (~3,500 species), are actually a clade that is nested within squamates (Streicher and Wiens 2017). The squamate lineage that is ancestral to snakes became limbless about 170 million years ago (see Hedges et al. 2006) – and also underwent a suite of changes to their head shape, digestive tract, and other traits associated with their limbless lifestyle. In other words, snakes are lizards – highly modified lizards, but lizards nonetheless. And snakes are not the only limbless lineage of squamates. In fact, lineages within squamates have lost their limbs over and over again through their history (e.g. Figure 7.1E and F), with some estimates that squamates have lost their limbs at least 26 times in the past 240 million years (Brandley et al. 2008).

Squamates, the clade that includes all living species of lizards, are well known for their diversity. From the gigantic Komodo dragon of Indonesia (Figure 7.1A, *Varanus komodoensis*) to tiny leaf chameleons of Madagascar (Figure 7.1B, *Brookesia*), squamates span an impressive range of form and ecological niche use (Vitt et al. 2003; Pianka et al. 2017). Even the snakes (Figure 7.1C and D), extraordinarily diverse in their own right (~3,500 species), are actually a clade that is nested within squamates (Streicher and Wiens 2017). The squamate lineage that is ancestral to snakes became limbless about 170 million years ago (see [@]) – and also underwent a suite of changes to their head shape, digestive tract, and other traits associated with their limbless lifestyle. In other words, snakes are lizards – highly modified lizards, but lizards nonetheless. And snakes are not the only limbless lineage of squamates. In fact, lineages within squamates have lost their limbs

over and over again through their history (e.g. Figure 7.1E and F), with some estimates that squamates have lost their limbs at least 26 times in the past 240 million years (Brändley et al. 2008).

Limblessness is an example of a discrete trait – a trait that can occupy one of a set of distinct character states. Analyzing the evolution of discrete traits requires a different modeling approach than what we used for continuous traits. In this chapter, I will discuss the Mk model (Lewis 2001), which is a general approach to modeling the evolution of discrete traits on trees. Fitting this model to comparative data will help us understand the evolution of traits like limblessness where species can be placed into one of a number of discrete character states.

Section 7.2: Modeling the evolution of discrete states

So far, we have only dealt with continuously varying characters. However, many characters of interest to biologists can best be described by characters with a set number of fixed states. For limblessness in squamates, each species is either legless (state 0) or not (state 1; actually, there are some species that might be considered “intermediate” Brändley et al. 2008, but we will ignore those for now). We might have particular questions about the evolution of limblessness in squamates. For example, how many times this character has changed in the evolutionary history of squamates? How often does limblessness evolve? Do limbs ever re-evolve? Is the evolution of limblessness related to some other aspect of the lives of these reptiles?

We will consider discrete characters where each species might exhibit one of k states. (In the limbless example above, $k = 2$). For characters with more than two states, there is a key distinction between ordered and unordered characters. Ordered characters can be placed in an order so that transitions only occur between adjacent states. For example, I might include “intermediate” species that are somewhere in between limbed and limbless – for example, the “mermaid skinks” (*Sirenoscinus*) from Madagascar, so called because they lack hind limbs (Figure 7.2, Moch and Senter 2011). An ordered model might only allow transitions between limbless and intermediate, and intermediate and limbed;

Figure 7.1. Squamates, legged and legless. A. Komodo dragon, B. Brookesia chameleon, C. False coral (*Oxyrhopus guibei*) and D. hognose snakes, E. a pygopodid - a limbless gecko and F. an anguid, another legless lizard. Photo credits: all from Wikipedia commons, photos by: A: Raul654, B. Brian Gratwicke, C. Gionorossi, D. Bladerunner8u, E. Smacdonald, F. Marek_bydg.

it would be impossible under such a model to go directly from limbed to limbless without first becoming intermediate. For unordered characters, any state can change into any other state. In this chapter, I will focus mainly on unordered characters; we will return to ordered characters later in the book.

Figure 7.2. Mermaid skink, from Wikipedia commons; photo by Aurélien Miralles.

Most work on the evolution of discrete characters on phylogenetic trees has focused on the evolution of gene or protein sequences. Gene sequences are made up of four character states (A, C, T, and G for DNA). Models of sequence evolution allow transitions among all of these states at certain rates, and may allow transition rates to vary across sites, among clades, or through time. There are a huge number of named models that have been applied to this problem (e.g. Jukes-Cantor, JC; General Time-Reversible, GTR; and many more, Yang 2006), and a battery of statistical approaches are available to fit these models to data (e.g. Posada 2008).

Any discrete character can be modeled in a similar way as gene sequences. When considering phenotypic characters, we should keep in mind two main differences from the analysis of DNA sequences. First, arbitrary discrete characters may have any number of states (beyond the four associated with DNA sequence data). Second, characters are

typically analyzed independently rather than combining long sets of characters and assuming that they share the same model of change.

Section 7.3: The Mk Model

The most basic model for discrete character evolution is called the Mk model. First developed for trait data by Pagel (1994; although the name Mk comes from Lewis 2001). The Mk model is a direct analogue of the Jukes-Cantor (JC) model for sequence evolution. The model applies to a discrete character having k unordered states. Such a character might have $k = 2$, $k = 3$, or even more states. Evolution involves changing between these k states (Figure 7.3).

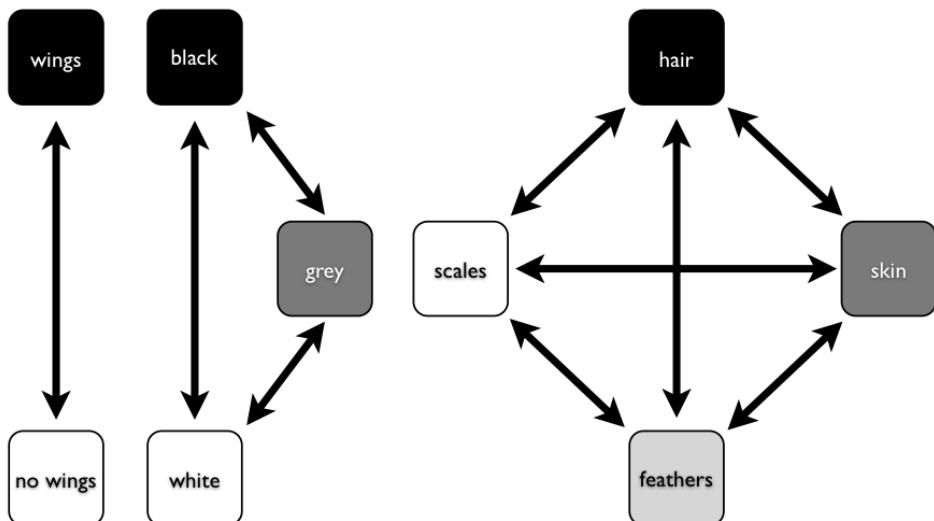

Figure 7.3. Examples of discrete characters with (A) $k = 2$, (B) $k = 3$, and (C) $k = 4$ states.

The basic version of the Mk model assumes that transitions among these states follow a Markov process. This means that the probability

of changing from one state to another depends only on the current state, and not on what has come before. For example, it makes no difference if a lineage has just evolved the trait of “feathers,” or whether they have had feathers for millions of years – the probability of evolving a different character state is the same in both cases. The basic Mk model also assumes that every state is equally likely to change to any other states.

For the basic Mk model, we can denote the instantaneous rate of change between states using the parameter q . In general, q_{ij} is called the instantaneous rate between character states i and j . It is defined as the limit of the rate measured over very short time intervals¹.

Again, for the basic Mk model, instantaneous rates between all pairs of characters are equal; that is, $q_{ij} = q_{mn}$ for all $i \neq j$ and $m \neq n$.

We can summarize general Markov models for discrete characters using a transition rate matrix (Lewis 2001):

(eq. 7.1)

$$\mathbf{Q} = \begin{bmatrix} -d_1 & q_{12} & \dots & q_{1k} \\ q_{21} & -d_2 & \dots & q_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ q_{k1} & q_{k2} & \dots & -d_k \end{bmatrix}$$

Note that the instantaneous rates are only entered into the off-diagonal parts of the matrix. Along the diagonal, these matrices always have a set of negative numbers. For any \mathbf{Q} matrix, the sum of all the elements in each row is zero – a necessary condition for a transition rate matrix. Because of this, each negative number has a value, d_i , equal to the sum of all of the other numbers in the row. For example,

(eq. 7.2)

$$d_1 = \sum_{i=2}^k q_{1i}$$

For a two-state Mk model, $k = 2$ and rates are symmetric so that $q_{12} = q_{21}$. In this case, we can write the transition rate matrix as:

(eq. 7.3)

$$\mathbf{Q} = \begin{bmatrix} -q & q \\ q & -q \end{bmatrix}$$

Likewise, for $k = 3$, the transition rate matrix is:

(eq. 7.4)

$$\mathbf{Q} = \begin{bmatrix} -2q & q & q \\ q & -2q & q \\ q & q & -2q \end{bmatrix}$$

In general, the k -state transition matrix for a basic M_k model is:

(eq. 7.5)

$$\mathbf{Q} = \begin{bmatrix} 1-k & 1 & \dots & 1 \\ 1 & 1-k & \dots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \dots & 1 \end{bmatrix}$$

Once we have this transition rate matrix, we can calculate the probability distribution of trait states after any time interval t using the equation (Lewis 2001):

(eq. 7.6)

$$\mathbf{P}(t) = e^{\mathbf{Qt}}$$

This equation looks simple, but calculating $P(t)$ involves matrix exponentiation – raising e to a power defined by a matrix. This calculation is substantially different from raising e to the power defined by each element of a matrix². The result is a matrix, \mathbf{P} , of transition probabilities. Each element in this matrix (p_{ij}) gives the probability that starting in state i you will end up in state j over that time interval t . For the standard M_k model, there is a general solution to this equation:

(eq. 7.7)

$$p_{ii}(t) = \frac{1}{k} + \frac{k-1}{k}e^{-kqt}$$

$$p_{ij}(t) = \frac{1}{k} - \frac{1}{k}e^{-kqt}$$

In particular, when $k = 2$,

(eq. 7.8)

$$p_{ii}(t) = \frac{1}{k} + \frac{k-1}{k} e^{-kqt} = \frac{1}{2} + \frac{2-1}{2} e^{-2qt} = \frac{1+e^{-2qt}}{2}$$
$$p_{ij}(t) = \frac{1}{k} - \frac{1}{k} e^{-kqt} = \frac{1}{2} - \frac{1}{2} e^{-2qt} = \frac{1-e^{-2qt}}{2}$$

If we consider what happens when time gets very large in these equations, we see an interesting pattern. Any term that has e^{-t} in it gets closer and closer to zero as t increases. Because of this, for all values of k , each $p_{ij}(t)$ converges to a constant value, $1/k$. This is the stationary distribution of character states, π , defined as the equilibrium frequency of character states if the process is run many times for a long enough time period. In general, the stationary distribution of an Mk model is:

(eq. 7.9)

$$\pi = [1/k \quad 1/k \quad \dots \quad 1/k]$$

In the case of $k = 2$,

(eq. 7.10)

$$\pi = [1/2 \quad 1/2]$$

Section 7.4: The Extended Mk Model

The Mk model assumes that transitions among all possible character states occur at the same rate. However, that may not be a valid assumption. For example, it is often supposed that it is easier to lose a complex character than to gain one. We might want to fit models that allow for such asymmetries in rates.

For models of DNA sequence evolution there are a wide range of models allowing different rates between distinct types of nucleotides (Yang 2006). Unequal rates are usually incorporated into the Mk model in two ways. First, one can consider the symmetric model (SYM; Paradis et al. 2004). In the symmetric model, the rate of change between any two character states is the same forwards as it is backwards (that is, rates of change are symmetric; $q_{ij} = q_{ji}$). The rate for a particular pair of states might differ from other pairs of character stats. Note that when $k = 2$ the symmetric model is identical to the basic Mk model.

The rate matrix for this model has as many free rate parameters as there are pairs of character states:

(eq. 7.11)

$$p = \frac{k(k - 1)}{2}$$

However, in general symmetric models will not have stationary distributions where all character states occur at equal frequencies, as noted above for the Mk model. We can account for these uneven frequencies by adding additional parameters to our model:

(eq. 7.12)

$$\pi_{SYM} = [\pi_1 \ \pi_2 \ \dots \ 1 - \sum_{i=1}^{n-1} \pi_i]$$

Note that we only have to specify $n - 1$ equilibrium frequencies, since we know that they all sum to one. We have added $n - 1$ new parameters, for a total number of parameters:

(eq. 7.13)

$$p = \frac{k(k - 1)}{2} + n - 1$$

To obtain a **Q**-matrix for this model, we combine the information from both the relative transition rates and equilibrium frequencies:

(eq. 7.14)

$$\mathbf{Q} = \begin{bmatrix} \cdot & r_1 & \dots & r_{n-1} \\ r_1 & \cdot & \dots & \vdots \\ \vdots & \vdots & \cdot & r_{k(k-1)/2} \\ r_{n-1} & \dots & r_{k(k-1)/2} & \cdot \end{bmatrix} \begin{bmatrix} \pi_1 & 0 & 0 & 0 \\ 0 & \pi_2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \pi_n \end{bmatrix}$$

In this equation I have left the diagonal of the first matrix as dots. The final **Q**-matrix\$ must have all rows sum to one, so one can adjust the values of that matrix after the multiplication step.

In the case of a two-state model, for example, we can create a model where the forward rate is double the backward rate, and the equilibrium frequency of character one is 0.75. Then:

(eq. 7.15)

$$\mathbf{Q} = \begin{bmatrix} \cdot & 1 \\ 2 & \cdot \end{bmatrix} \begin{bmatrix} 0.75 & 0 \\ 0 & 0.25 \end{bmatrix} = \begin{bmatrix} \cdot & 0.25 \\ 1.5 & \cdot \end{bmatrix} = \begin{bmatrix} -0.25 & 0.25 \\ 1.5 & -1.5 \end{bmatrix}$$

It is worth noting that this approach of setting parameters that define equilibrium state frequencies, although borrowed from molecular evolution, is not completely standard in the comparative methods literature. One also sees equilibrium frequencies treated as a fixed property of the model, and assumed to be either equal across states or tied directly to the parameters in the \mathbf{Q} -matrix.

The second common extension of the Mk model is called the all-rates-different model (ARD; Paradis et al. 2004). In this model every possible type of transition can have a different rate. There are thus $k(k - 1)$ free rate parameters for this model, and again $n - 1$ parameters to specify the equilibrium frequencies of the character states.

The same algorithm can be used to calculate the likelihood for both of these extended Mk models (SYM and ARD). These models have more parameters than the standard Mk. To find maximum likelihood solutions, we must optimize the likelihood across the entire set of unknown parameters (see Chapter 7).

Section 7.5: Simulating the Mk model on a tree

We can also use the equations above to simulate evolution under an Mk or extended-Mk model on a tree (Felsenstein 2004). To do this, we simulate character evolution on each branch of the tree, starting at the root and progressing towards the tips. At speciation, we assume that both daughter species inherit the character state of their parental species immediately following speciation, and then evolve independently after that. At the end of the simulation, we will obtain a set of character states, one for each tip in the tree. The distribution of character states will depend on the shape of the phylogenetic tree (both its topology and branch lengths) along with the parameters of our model of character evolution.

We first draw a beginning character state at the root of the tree. There are several common ways to do this. For example, we can either draw from the stationary distribution or from one where each character state is equally likely. In the case of the standard Mk model, these are the same. For example, if we are simulating evolution under Mk with $k = 2$, then state 0 and 1 each have a probability of $1/2$ at the root. We can draw the root state from a binomial distribution with $p_{state_0} = 0.5$.

Once we have a character state for the root, we then simulate evolution along each branch in the tree. We start with the (usually two) branches descending from the root. We then proceed up the tree, branch by branch, until we get to the tips.

We can understand this algorithm perfectly well by thinking about what happens on each branch of the tree, and then extending that algorithm to all of the branches (as described above). For each branch, we first calculate $\mathbf{P}(t)$, the transition probability matrix, given the length of the branch and our model of evolution as summarized by \mathbf{Q} and the branch length t . We then focus on the row of $\mathbf{P}(t)$ that corresponds to the character state at the beginning of the branch. For example, let's consider a basic two-state Mk model with $q = 0.5$. We will call the states 0 and 1. We can calculate $\mathbf{P}(t)$ for a branch with length $t = 3$ as:

(eq. 7.16)

$$\mathbf{P}(t) = e^{\mathbf{Qt}} = \exp\left(\begin{bmatrix} -0.5 & 0.5 \\ 0.5 & -0.5 \end{bmatrix} \cdot 3\right) = \begin{bmatrix} 0.525 & 0.475 \\ 0.475 & 0.525 \end{bmatrix}$$

If we had started with character state 0 at the beginning of this branch, we would focus on the first row of this matrix. We want to end up at state 0 with probability 0.525 and change to state 1 with probability 0.475. We again draw a uniform random deviate u , and choose state 0 if $0 \leq u < 0.525$ and state 1 if $0.525 \leq u < 1$. If we started with a different character state, we would use a different row in the matrix. If this is an internal branch in the tree, then both daughter species inherit the character state that we chose immediately following speciation – but might diverge soon after! By repeating this along every branch in the tree, we obtain a set of character states at the tips of the tree. This is then the output of our simulation.

Two additional details here are worth noting. First, the procedure for simulating characters under the extended-Mk model are identical to those above, except that the calculation of matrix exponentials is more complicated than in the standard Mk model. Second, if you are simulating a character with more than two states, then the procedure for drawing a random number is slightly different³.

We can apply this approach to simulate the evolution of limblessness in squamates. Below, I present the results of three such simulations. These simulations are a little different than what I describe above because they consider all changes in the tree, rather than just character states at nodes and tips; but the model (and the principal) is the same. You can see that the model leaves an imprint on the pattern of changes in the tree, and you can imagine that one might be able to reconstruct the model using a phylogenetic comparative approach. Of course, typically we know only the tip states, and have to reconstruct changes along branches in the tree. We will discuss parameter estimation for the Mk and extended-Mk models in the next chapter.

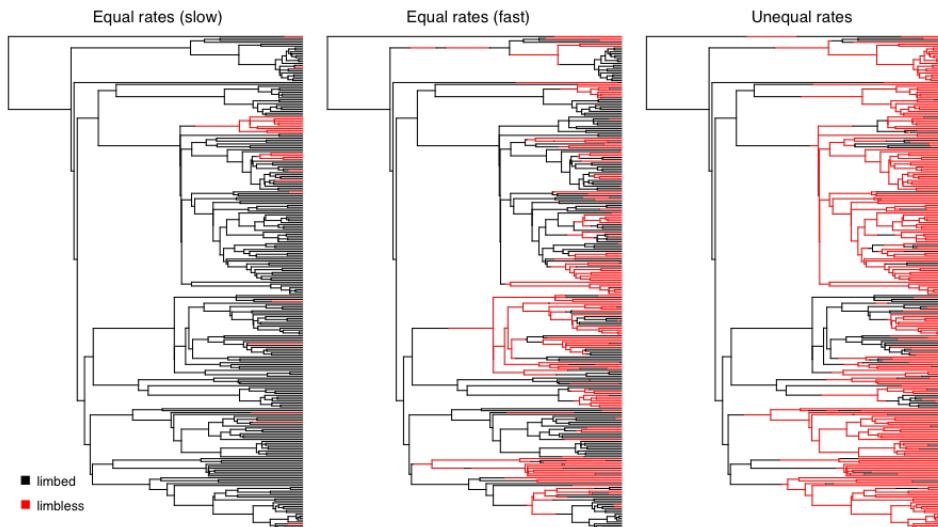

Figure 7.4. Simulated character evolution on a phylogenetic tree of squamates (from Brandley et al. 2008) under an equal-rates Mk model with slow, fast, and asymmetric transition rates (from right to left). In all three cases, I assumed that the ancestor of squamates had limbs.

Section 7.6: Chapter summary

In this chapter I have described the Mk model, which can be used to describe the evolution of discrete characters that have a set number of fixed states. We can also elaborate on the Mk model to allow more complex models of discrete character evolution (the extended-Mk model). These models can all be used to simulate the evolution of discrete characters on trees.

In summary, the Mk and extended Mk model are general models that one can use for the evolution of discrete characters. In the next chapter, I will show how to fit these models to data and use them to test evolutionary hypotheses.

Section 7.7: Footnotes

1: Imagine that you calculate a rate of character change by counting the number of changes of state of a character over some time interval, t . You can calculate the rate of change as $n_{changes}/t$. The instantaneous rate is the value that this rate approaches as t gets smaller and smaller so that the time interval is nearly zero.

2: I will not cover the details of matrix exponentiation here – interested readers should see Yang (2006) for details – but the calculations are not trivial.

3: One still obtains the relevant row from $\mathbf{P}(t)$ and draws a uniform random deviate u . Imagine that we have a ten-state character with states 0 - 9. We start at state 0 at the beginning of the simulation. Again using $q = 0.5$ and $t = 3$, we find that:

(eq. 7.17)

$$p_{ii}(t) = \frac{1}{k} + \frac{k-1}{k}e^{-kqt} = \frac{1}{10} + \frac{9}{10}e^{-2 \cdot 0.5 \cdot 3} = 0.145$$
$$p_{ij}(t) = \frac{1}{k} - \frac{1}{k}e^{-kqt} \frac{1}{10} - \frac{1}{10}e^{-2 \cdot 0.5 \cdot 3} = 0.095$$

We focus on the first row of $\mathbf{P}(t)$, which has elements:

We calculate the cumulative sum of these elements, adding them together so that each number represents the sum of itself and all preceding elements in the vector:

Now we compare u to the numbers in this cumulative sum vector. We select the smallest element that is still strictly larger than u , and assign this character state for the end of the branch. For example, if $u = 0.475$, the 5th element, 0.525, is the smallest number that is still greater than u . This corresponds to character state 4, which we assign to the end of the branch. This last procedure is a numerical trick. Imagine that we have a line segment with length 1. The cumulative sum vector breaks the unit line into segments, each of which is exactly as long as the probability of each event in the set. One then just draws a random number between 0 and 1 using a uniform distribution. The segment that contains this random number is our event.

Chapter 8: Fitting models of discrete character evolution

Section 8.1: The evolution of limbs and limblessness

In the introduction to Chapter 7, I mentioned that squamates had lost their limbs repeatedly over their evolutionary history. This is a pattern that has been known for decades, but analyses have been limited by the lack of a large, well-supported species-level phylogenetic tree of squamates (but see Brandley et al. 2008). Only in the past few years have phylogenetic trees been produced at a scale broad enough to take a comprehensive look at this question [e.g. Bergmann and Irschick (2012); Pyron et al. (2013); see Figure 8.1]. Such efforts to reconstruct this section of the tree of life provide exciting potential to revisit old questions with new data.

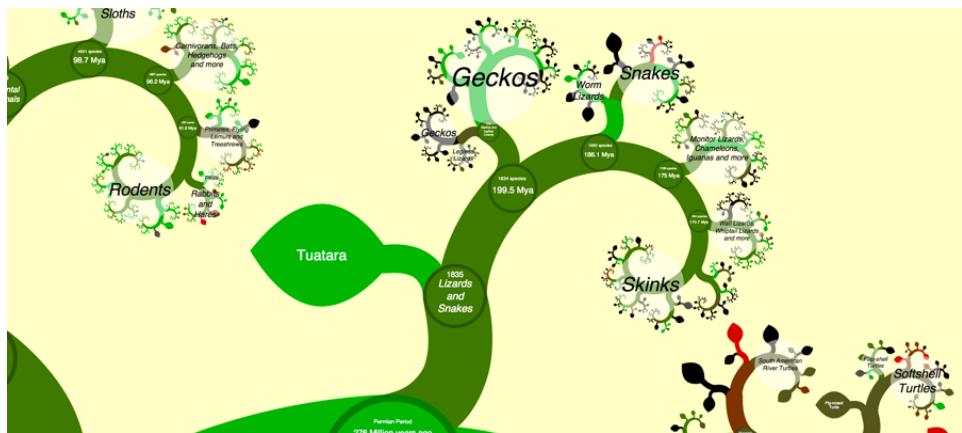

Figure 8.1. A view of the squamate tree of life. Data from Bergmann et al. (2012), visualized using OneZoom [Rosindell and Harmon (2012); see www.onezoom.org].

Plotting the pattern of limbed and limbless species on the tree leads to interesting questions about the tempo and mode of this trait in squamates. For example, are there multiple gains as well as losses of limbs? Do gains and losses happen at the same rate, or (as we might expect) are gains more rare than losses? We can test hypothesis such

as these using the the Mk and extended-Mk models (see chapter 7). In this chapter we will fit these models to phylogenetic comparative data.

Section 8.2: Fitting Mk models to comparative data

The equations in Chapter 7 give us enough information to calculate the likelihood for comparative data on a tree. To understand how this is done, we can first consider the simplest case, where we know the beginning state of a character, the branch length, and the end state. We can then apply the method across an entire tree using a pruning algorithm, which will allow calculation of the likelihood of the data given the model and phylogenetic tree.

Imagine that a two-state character changes from a state of 0 to a state of 1 sometime over a time interval of $t = 3$. What is the likelihood of these data under the Mk model? As we did in equation 7.17, we can set a rate parameter $q = 0.5$ to calculate a probability matrix:

(eq. 8.1)

$$\mathbf{P}(t) = e^{\mathbf{Qt}} = \exp\left(\begin{bmatrix} -0.5 & 0.5 \\ 0.5 & -0.5 \end{bmatrix} \cdot 3\right) = \begin{bmatrix} 0.525 & 0.475 \\ 0.475 & 0.525 \end{bmatrix}$$

For this simple example, we started with state 0, so we look at the first row. Along this branch, we ended at state 1, so we should look specifically at $p_{12}(t)$: the probability of starting with state 0 and ending with state 1 over time t . This value is the probability of obtaining the data given the model (i.e. the likelihood): $L = 0.475$.

This likelihood applies to the evolutionary process along this single branch.

When we have comparative data the situation is more complex. If we knew the ancestral character states and states at every node in the tree, then calculation of the overall likelihood would be straightforward – we could just apply the approach above many times, once for each branch of the tree. However, there are two problems. First, we don't know the starting state of the character at the root of the tree, and must treat that as an unknown. Second, we are modeling a process

that is happening independently on many branches in a phylogenetic tree, and only observe the states at the end of these branches. All of the character states at internal nodes of the tree are unknown. The likelihood that we want to calculate has to be summed across all of these unknown character state possibilities on the internal branches of the tree.

Thankfully, Felsenstein (1973) provides an elegant algorithm for calculating the likelihoods for discrete characters on a tree. This algorithm, called Felsenstein's pruning algorithm, is described with an example in the appendix to this chapter. Felsenstein's pruning algorithm was important in the history of phylogenetics because it allowed scientists to efficiently calculate the likelihoods of comparative data given a tree and a model. One can then maximize that likelihood by changing model parameters (and perhaps also the topology and branch lengths of the tree; see Felsenstein 2004).

Pruning also gives some insight into how we can calculate probabilities on trees; many other problems in comparative methods can be approached using different pruning algorithms.

Felsenstein's pruning algorithm proceeds backwards in time from the tips to the root of the tree (see appendix, section 8.8). At the root, we must specify the probabilities of each character state in the common ancestor of the species in the clade. As mentioned in Chapter 7, there are at least three possible methods for doing this. First, one can assume that each state can occur at the root with equal probability. Second, one can assume that the states are drawn from their stationary distribution, as given by the model. The stationary distribution is a stable probability distribution of states that is reached by the model after a long amount of time. Third, one might have some information about the root state – perhaps from fossils, or information about character states in a set of outgroup taxa – that can be used to assign probabilities to the states. In practice, the first two of these methods are more common. In the case discussed above – an Mk model with all transition rates equal – the stationary distribution is one where all states are equally probable, so the first two methods are identical. In general, though, these three methods can give different results.

Section 8.3: Using maximum likelihood to estimate parameters of the Mk model

The algorithm in the appendix below gives the likelihood for any particular discrete-state Markov model on a tree, but requires us to specify a value of the rate parameter q . In the example given, this rate parameter $q = 1.0$ corresponds to a $\ln L$ of -6.5. But is this the best value of q to use for our Mk model? Probably not. We can use maximum likelihood to find a better estimate of this parameter.

If we apply the pruning algorithm across a range of different values of q , the likelihood changes. To find the ML estimate of q , we can again use numerical optimization methods, calculating the likelihood by pruning for many values of q and finding the maximum.

Applying this method to the lizard data, we obtain a maximum likelihood estimate of $q = 0.001850204$ corresponding to $\ln L = -80.487176$.

The example above considers maximization of a single parameter, which is a relatively simple problem. When we extend this to a multi-parameter model – for example, the extended Mk model will all rates different (ARD) – maximizing the likelihood becomes much more difficult. R packages solve this problem by using sophisticated algorithms and applying them multiple times to make sure that the value found is actually a maximum.

Section 8.4: Using Bayesian MCMC to estimate parameters of the Mk model

We can also analyze this model using a Bayesian MCMC framework. We can modify the standard approach to Bayesian MCMC (see chapter 2):

1. Sample a starting parameter value, q , from its prior distributions. For this example, we can set our prior distribution as uniform between 0 and 1. (Note that one could also treat probabilities of states at the root as a parameter to be estimated from the data; in this case we will assign equal probabilities to each state).

2. Given the current parameter value, select new proposed parameter values using the proposal density $Q(q'|q)$. For example, we might use a uniform proposal density with width 0.2, so that $Q(q'|q) \sim U(q - 0.1, q + 0.1)$.
3. Calculate three ratios:
 - a. The prior odds ratio, R_{prior} . In this case, since our prior is uniform, $R_{prior} = 1$.
 - b. The proposal density ratio, $R_{proposal}$. In this case our proposal density is symmetrical, so $R_{proposal} = 1$.
 - c. The likelihood ratio, $R_{likelihood}$. We can calculate the likelihoods using Felsenstein's pruning algorithm (Box 8.1); then calculate this value based on equation 2.26.
4. Find R_{accept} as the product of the prior odds, proposal density ratio, and the likelihood ratio. In this case, both the prior odds and proposal density ratios are 1, so $R_{accept} = R_{likelihood}$
5. Draw a random number u from a uniform distribution between 0 and 1. If $u < R_{accept}$, accept the proposed value of both parameters; otherwise reject, and retain the current value of the two parameters.
6. Repeat steps 2-5 a large number of times.

We can run this analysis on our squamate data, obtaining a posterior with a mean estimate of $q = 0.001980785$ and a 95% credible interval of $0.001174813 - 0.003012715$.

Section 8.5: Exploring Mk: the “total garbage” test

One problem that arises sometimes in maximum likelihood optimization happens when instead of a peak, the likelihood surface has a long flat “ridge” of equally likely parameter values. In the case of the Mk model, it is common to find that all values of q greater than a certain value have the same likelihood. This is because above a certain rate, evolution has been so rapid that all traces of the history of evolution of that character have been obliterated. After this point, character states

of each lineage are random, and have no relationship to the shape of the phylogenetic tree. Our optimization techniques will not work in this case because there is no value of q that has a higher likelihood than other values. Once we get onto the ridge, all values of q have the same likelihood.

For Mk models, there is a simple test that allows us to recognize when the likelihood surface has a long ridge, and q values cannot be estimated. I like to call this test the “total garbage” test because it can tell you if your data are “garbage” with respect to historical inference – that is, your data have no information about historical patterns of trait change. One can predict states just as well by choosing each species at random.

To carry out the total garbage test, imagine that you are just drawing trait values at random. That is, each species has some probability p of having character state 0, and some probability $(1 - p)$ of having state 1 (one can also generalize this test to multi-state models). This likelihood is easy to write down. For a tree of size n , the probability of drawing n_0 species with state 0 is:

(eq. 8.2)

$$L_{garbage} = p^{n_0} (1 - p)^{n - n_0}$$

This equation gives the likelihood of the “total garbage” model for any value of p . Equation 8.10 is related to a binomial distribution (lacking only the factorial term). We also know from probability theory that the ML estimate of p is n_0/n , with likelihood given by the above formula.

Now consider the likelihood surface of the Mk model. When Mk likelihood surfaces have long ridges, they are nearly always for high values of q – and when the transition rate of character changes is high, this model converges to our “drawing from a hat” (or “garbage”) model. The likelihood ridge lies at the value that is exactly taken from equation 8.10 above.

Thus, one can compare the likelihood of our Mk model to the total garbage model. If the maximum likelihood value of q has the same likelihood as our garbage model, then we know that we are on a ridge of the likelihood surface and q cannot be estimated. We also have no ability to make any statements about the past evolution of our

character – in particular, we cannot estimate ancestral character state with any precision. By contrast, if the likelihood of the Mk model is greater than the total garbage model, then our data contains some historical information. We can also make this comparison using AIC, considering the total garbage model as having a single parameter p .

For the squamates, we have $n = 258$ and $n_0 = 207$. We calculate $p = n_0/n = 207/258 = 0.8023256$. So the likelihood of our garbage model is $L_{garbage} = p^{n_0}(1-p)^{n-n_0} = 0.8023256^{207}(1-0.8023256)^{51} = 1.968142e-56$. This calculation is both easier and more useful, though, on a natural-log scale: $\ln L_{garbage} = n_0 \cdot \ln(p) + (n - n_0) \cdot \ln(1 - p) = 207 \cdot \ln(0.8023256) + 51 \cdot \ln(1 - 0.8023256) = -128.2677$. Compare this to the log-likelihood of our Mk model, $\ln L = -80.487176$, and you will see that the garbage model is a terrible fit to these data. There is, in fact, some historical information about species' traits in our data.

Section 8.6: Testing for differences in the forwards and backwards rate of character change

I have been referring to an example of lizard limb evolution throughout this chapter, but we have not yet tested the hypothesis that I stated in the introduction: that transition rates for losing limbs are higher than rates of gaining limbs.

To do this, we can compare our one-rate Mk model with a two-rate model with differences in the rate of forwards and backwards transitions. This is a special case of the “all-rates different” model discussed in chapter two. Q matrices for these two models will be, for model 1 (equal rates):

(eq. 8.3)

$$\mathbf{Q}_{\mathbf{E}}\mathbf{R} = \begin{bmatrix} -q & q \\ q & -q \end{bmatrix}$$

And for model 2, asymmetric:

(eq. 8.4)

$$\mathbf{Q_A SY} = \begin{bmatrix} -q_1 & q_1 \\ q_2 & -q_2 \end{bmatrix}$$

Notice that the ER model has one parameter, while the ASY model has two. Also we have specified equal probabilities of each character at the root of the tree, which may not be justified. But this comparison is still useful as a simple example.

One can compare the two nested models using standard methods discussed in previous chapters – that is, a likelihood-ratio test, AIC, BIC, or other similar methods.

We can apply all of the above methods to analyze the evolution of limblessness in squamates. We can use the tree and character state data from Brändley et al. (2008), which is plotted with ancestral state reconstructions as Figure 8.2.

If we fit an Mk model to these data assuming equal state frequencies at the root of the tree, we obtain a lnL of -80.5 and an estimate of the Q_{ER} matrix as:

(eq. 8.5)

$$\mathbf{Q_E R} = \begin{bmatrix} -0.0019 & 0.0019 \\ 0.0019 & -0.0019 \end{bmatrix}$$

The ASY model with different forward and backward rates gives a lnL of -79.4 and:

(eq. 8.6)

$$\mathbf{Q_A SY} = \begin{bmatrix} -0.0016 & 0.0016 \\ 0.0038 & -0.0038 \end{bmatrix}$$

Note that the ASY model has a higher backwards than forwards rate; as expected, we estimate a rate of losing limbs that is higher than the rate of gaining them (although the difference is surprisingly low). Is this statistically supported? We can compare the AIC scores of the two models. For the ER model, $AIC_c = 163.0$, while for the ASY model $AIC_c = 162.8$. The AICc score is higher for the unequal rates model,

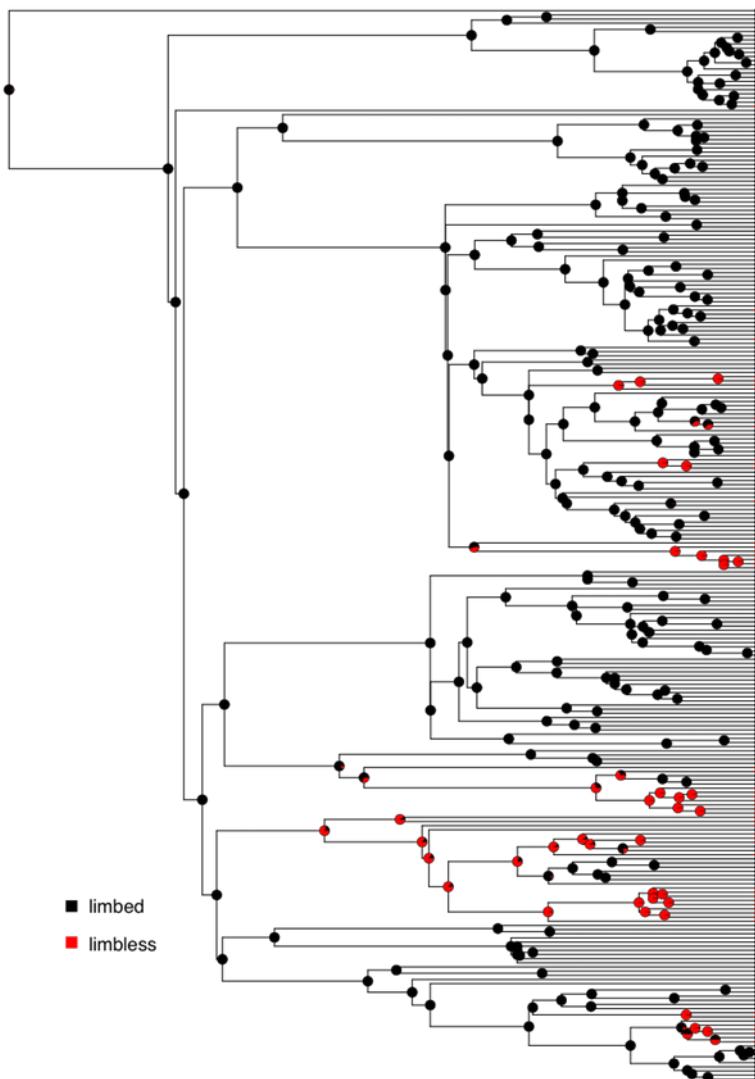

Figure 8.2. Reconstructed patterns of the evolution of limbs and limblessness across squamates. Tips show states of extant taxa (here, I classified species with neither fore- nor hindlimbs as limbless, which is conservative given the variation across this clade (see chapter 7). Pie charts on internal nodes show proportional marginal likelihoods for ancestral state reconstruction. Data from Brandley et al. (2008)

but only by about 0.2 – which is not definitive either way. So based on this analysis, we cannot rule out the possibility that forward and backward rates are equal.

A Bayesian analysis of the ASY model gives similar conclusions (Figure 8.3). We can see that the posterior distribution for the backwards rate (q_{21}) is higher than the forwards rate (q_{12}), but that the two distributions are broadly overlapping.

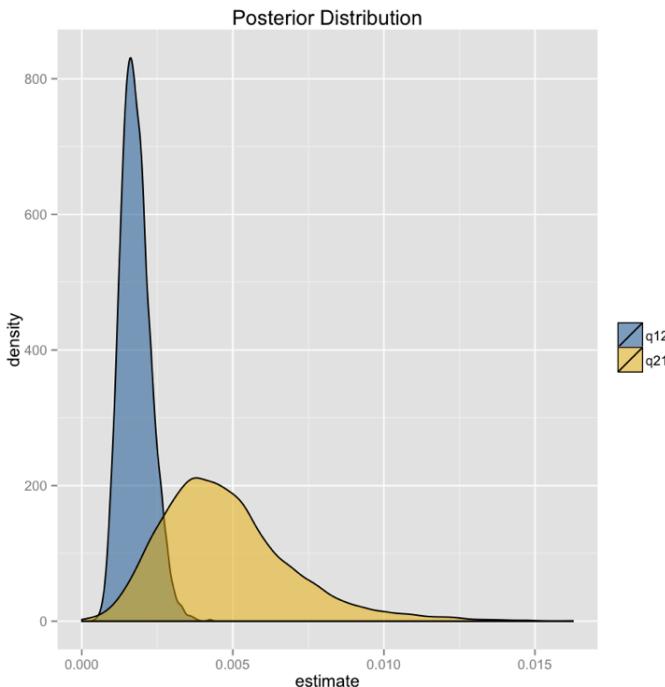

Figure 8.3. Bayesian posterior distributions for the extended-Mk model applied to the evolution of limblessness in squamates.

You might wonder about how we can reconcile these results, which suggest that squamates gain limbs at least as frequently as they lose them, with our biological intuition that limbs should be much more difficult to gain than they are to lose. But keep in mind that our comparative analysis is not using any information other than the states of extant species to reconstruct these rates. In particular, identifying irreversible evolution using comparative methods is a problem that is

known to be quite difficult, and might require outside information in order to resolve conclusively. For example, if we had some information about the relative number of mutational steps required to gain and lose limbs, we could use an informative prior – which would, I suspect, suggest that limbs are more difficult to gain than they are to lose. Such a prior could dramatically alter the results presented in Figure 8.3. We will return to the problem of irreversible evolution later in the book (Chapter 13).

Section 8.7: Chapter summary

In this chapter I describe how Felsenstein’s pruning algorithm can be used to calculate the likelihoods of Mk and extended-Mk models on phylogenetic trees. I have also described both ML and Bayesian frameworks that can be used to test hypotheses about character evolution. This chapter also includes a description of the “total garbage” test, which will tell you if your data has information about evolutionary rates of a given character.

Analyzing our example of lizard limbs shows the power of this approach; we can estimate transition rates for this character over macroevolutionary time, and we can say with some certainty that transitions between limbed and limbless have been asymmetric. In the next chapter, we will build on the Mk model and further develop our comparative toolkit for understanding the evolution of discrete characters.

Section 8.8: Appendix: Felsenstein’s pruning algorithm

Felsenstein’s pruning algorithm (1973) is an example of dynamic programming, a type of algorithm that has many applications in comparative biology. In dynamic programming, we break down a complex problem into a series of simpler steps that have a nested structure. This allows us to reuse computations in an efficient way and speeds up the time required to make calculations.

The best way to illustrate Felsenstein’s algorithm is through an example, which is presented in the panels below. We are trying to calculate

the likelihood for a three-state character on a phylogenetic tree that includes six species.

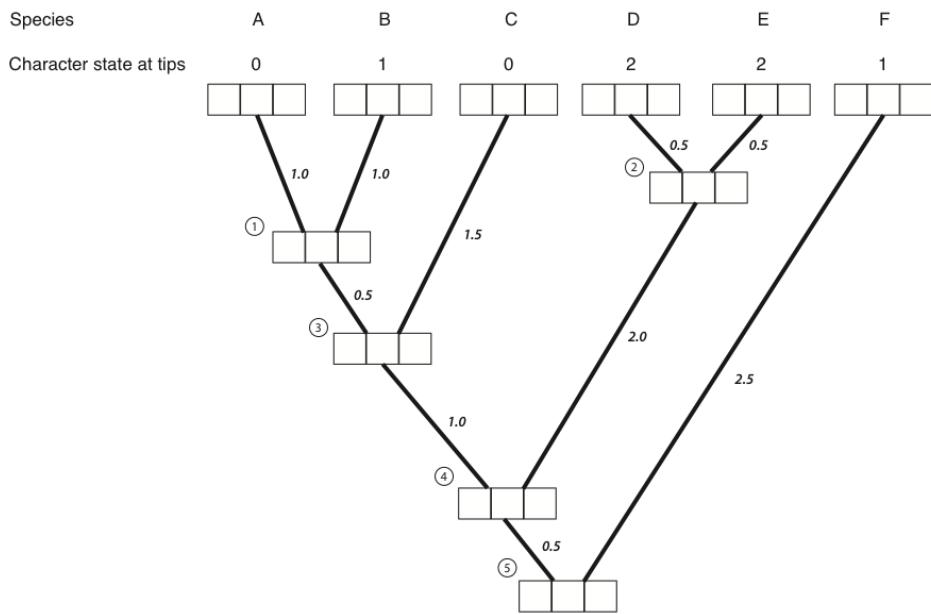

Figure 8.4A. Each tip and internal node in the tree has three boxes, which will contain the probabilities for the three character states at that point in the tree. The first box represents a state of 0, the second state 1, and the third state 2.

1. The first step in the algorithm is to fill in the probabilities for the tips. In this case, we know the states at the tips of the tree. Mathematically, we state that we know precisely the character states at the tips; the probability that that species has the state that we observe is 1, and all other states have probability zero:
2. Next, we identify a node where all of its immediate descendants are tips. There will always be at least one such node; often, there will be more than one, in which case we will arbitrarily choose one. For this example, we will choose the node that is the most recent common ancestor of species A and B, labeled as node 1 in Figure 8.2B.

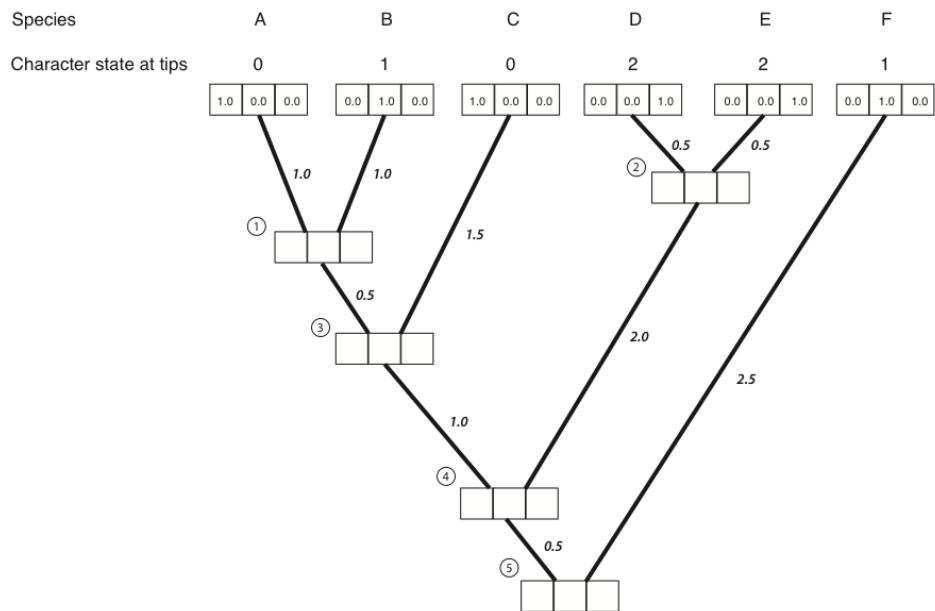

Figure 8.4B. We put a one in the box that corresponds to the actual character state and zeros in all others.

3. We then use equation 7.6 to calculate the conditional likelihood for each character state for the subtree that includes the node we chose in step 2 and its tip descendants. For each character state, the conditional likelihood is the probability, given the data and the model, of obtaining the tip character states if you start with that character state at the root. In other words, we keep track of the likelihood for the tipward parts of the tree, including our data, if the node we are considering had each of the possible character states. This calculation is:

(eq. 8.7)

$$L_P(i) = \left(\sum_{x \in k} Pr(x|i, t_L) L_L(x) \right) \cdot \left(\sum_{x \in k} Pr(x|i, t_R) L_R(x) \right)$$

Where i and x are both indices for the k character states, with sums taken across all possible states at the branch tips (x), and terms calculated for each possible state at the node (i). The two pieces of the equation are the left and right descendant of the node of interest. Branches can be assigned as left or right arbitrarily without affecting the final outcome, and the approach also works for polytomies (but the equation is slightly different). Furthermore, each of these two pieces itself has two parts: the probability of starting and ending with each state along the two branches being considered, and the current conditional likelihoods that enter the equation at the tips of the subtree ($L_L(x)$ and $L_R(x)$). Branch lengths are denoted as t_L and t_R for the left and right, respectively.

One can think of the likelihood “flowing” down the branches of the tree, and conditional likelihoods for the left and right branches get combined via multiplication at each node, generating the conditional likelihood for the parent node for each character state ($L_P(i)$).

Consider the subtree leading to species A and B in the example given. The two tip character states are 0 (for species A) and 1 (for species B). We can calculate the conditional likelihood for character state 0 at node 1 as:

(eq. 8.8)

$$L_P(0) = \left(\sum_{x \in k} Pr(x|0, t_L = 1.0) L_L(x) \right) \cdot \left(\sum_{x \in k} Pr(x|0, t_R = 1.0) L_R(x) \right)$$

Next, we can calculate the probability terms from the probability matrix \mathbf{P} . In this case $t_L = t_R = 1.0$, so for both the left and right branch:

(eq. 8.9)

$$\mathbf{Q}t = \begin{bmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{bmatrix} \cdot 1.0 = \begin{bmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{bmatrix}$$

So that: (eq. 8.10)

$$\mathbf{P} = e^{Qt} = \begin{bmatrix} 0.37 & 0.32 & 0.32 \\ 0.32 & 0.37 & 0.32 \\ 0.32 & 0.32 & 0.37 \end{bmatrix}$$

Now notice that, since the left character state is known to be zero, $L_L(0) = 1$ and $L_L(1) = L_L(2) = 0$. Similarly, the right state is one, so $L_R(1) = 1$ and $L_R(0) = L_R(2) = 0$.

We can now fill in the two parts of equation 8.2:

(eq. 8.11)

$$\sum_{x \in k} Pr(x|0, t_L = 1.0)L_L(x) = 0.37 \cdot 1 + 0.32 \cdot 0 + 0.32 \cdot 0 = 0.37$$

and

So:

(eq. 8.12)

$$L_P(0) = 0.37 \cdot 0.32 = 0.12.$$

This means that under the model, if the state at node 1 were 0, we would have a likelihood of 0.12 for this small section of the tree. We can use a similar approach to find that:

(eq. 8.13)

$$L_P(1) = 0.32 \cdot 0.37 = 0.12.$$

Now we have the likelihood for all three possible ancestral states. These numbers can be entered into the appropriate boxes:

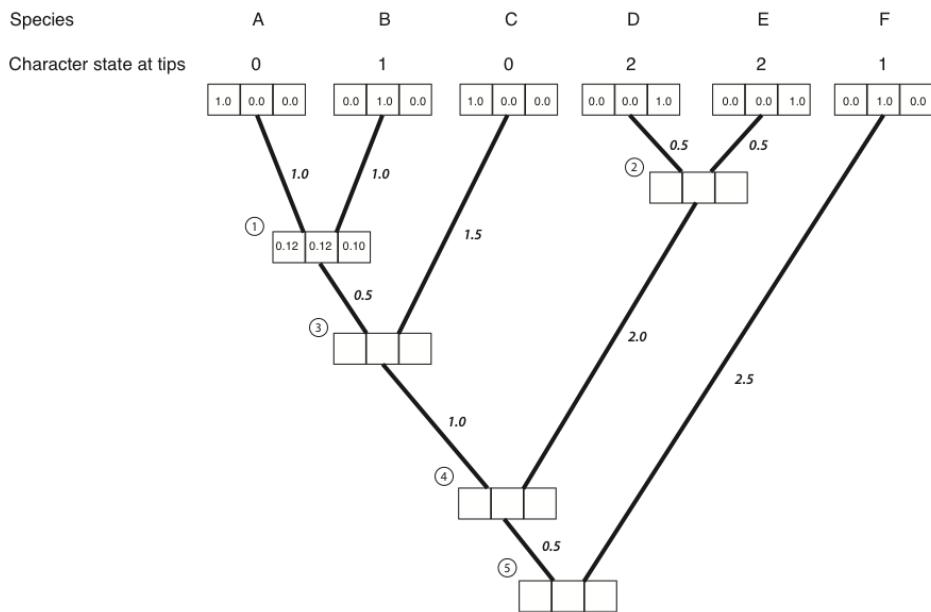

Figure 8.4C. Conditional likelihoods entered for node 1.

4. We then repeat the above calculation for every node in the tree. For nodes 3-5, not all of the $L_L(x)$ and $L_R(x)$ terms are zero; their values can be read out of the boxes on the tree. The result of all of these calculations:
5. We can now calculate the likelihood across the whole tree using the conditional likelihoods for the three states at the root of the tree.

(eq. 8.14)

$$L = \sum_{x \in k} \pi_x L_{root}(x)$$

Where π_x is the prior probability of that character state at the root of the tree. For this example, we will take these prior probabilities to be uniform, equal for each state ($\pi_x = 1/k = 1/3$). The likelihood for our example, then, is:

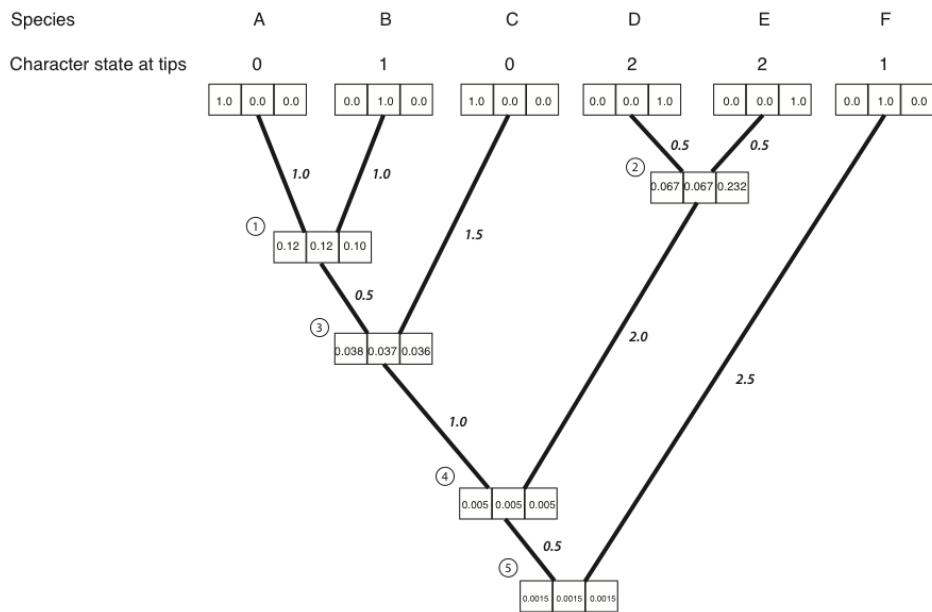

Figure 8.4D. Conditional likelihoods entered for all nodea.

(eq. 8.15)

$$L = 1/3 \cdot 0.00150 + 1/3 \cdot 0.00151 + 1/3 \cdot 0.00150 = 0.00150$$

Note that if you try this example in another software package, like GEIGER or PAUP*, the software will calculate a ln-likelihood of -6.5, which is exactly the natural log of the value calculated here.

Chapter 9: Beyond the Mk Model

Section 9.1: The Evolution of Frog Life History Strategies

Frog reproduction is one of the most bizarrely interesting topics in all of biology. Across the nearly 6,000 species of living frogs, one can observe a bewildering variety of reproductive strategies and modes (Zamudio et al. 2016). As children, we learn of the “classic” frog life history strategy: the female lays jellied eggs in water, which hatch into tadpoles, then later metamorphose into their adult form [e.g. Rey (2007); Figure 9.1A]. But this is really just the tip of the frog reproduction iceberg. Many species have direct development, where the tadpole stage is skipped and tiny froglets hatch from eggs. There are foam-nesting frogs, which hang their eggs from leaves in foamy sacs over streams; when the eggs hatch, they drop into the water [e.g. Fukuyama (1991); Figure 9.1B]. Male midwife toads carry fertilized eggs on their backs until they are ready to hatch, at which point they wade into water and their tadpoles wriggle free [Marquez and Verrell (1991); Figure 9.1C]. Perhaps most bizarre of all are the gastric-brooding frogs, now thought to be extinct. In this species, female frogs swallow their fertilized eggs, which hatch and undergo early development in their mother’s stomach (Tyler and Carter 1981). The young were then regurgitated to start their independent lives.

The great diversity of frog reproductive modes brings up several key questions that can potentially be addressed via comparative methods. How rapidly do these different types of reproductive modes evolve? Do they evolve more than once on the tree? Were “ancient” frogs more flexible in their reproductive mode than more recent species? Do some clades of frog show more flexibility in reproductive mode than others?

Many of the key questions stated above do not fall neatly into the Mk or extended-Mk framework presented in the previous chapters. In this chapter, I will review approaches that elaborate on this framework and allow scientists to address a broader range of questions about the evolution of discrete traits.

Figure 9.1. Examples of frog reproductive modes. (A) European common frogs lay jellied eggs in water, which hatch as tadpoles and metamorphose; (B) Malabar gliding frogs make nests that, supported by foam created during amplexus, hang from leaves and branches; (C) Male midwife toads carry fertilized eggs on their back. Photo credits: all from Wikipedia commons, photos by: A: Thomas Brown, B: Vikram Gupchup, C: Christian Fischer

To explore these questions, I will refer to a dataset of frog reproductive modes from Gomez-Mestre et al. (2012), specifically data classifying species as those that lay eggs in water, lay eggs on land without direct development (terrestrial), and species with direct development (Figure 9.2).

Section 9.2: Beyond the Mk model

In Chapter 8, we considered the evolution of discrete characters on phylogenetic trees. These models fall under the general category of continuous-time Markov models, which consider a process that can occupy two or more states. Transitions occur between those states in continuous time. The Markov property means that, at some time t , what happens next in the model depends only on the current state of the process and not on anything that came before.

In evolutionary biology, the most detailed work on continuous time Markov models has focused on DNA or protein sequence data. As mentioned earlier, an extremely large set of models are available for modeling and analyzing these molecular sequences. One can also elaborate on these models by adding rate heterogeneity across sites (e.g. the gamma parameter, as in GTR + Γ), or other complications related to mechanisms of sequence evolution (for a review, see Liò and Goldman 1998).

However, there are two important differences between models of sequence evolution and models of character change on trees that make our task distinct from the task of modeling DNA or amino acid sequences. First, when analyzing molecular sequences, one typically has data for many thousands (or millions) of characters. Data sets for other characters – like the phenotypic characters of species – are typically much smaller (and harder to collect). Second, sequence analysis very often assumes that each character evolves independently from all other characters, but that all characters (or at least certain large subsets of those characters) evolve under a shared model (Liò and Goldman 1998; Yang 2006). This means that, for example, the frequency of transitions between A and C at one location in a gene sequence contribute information about the same transition in a different location in the

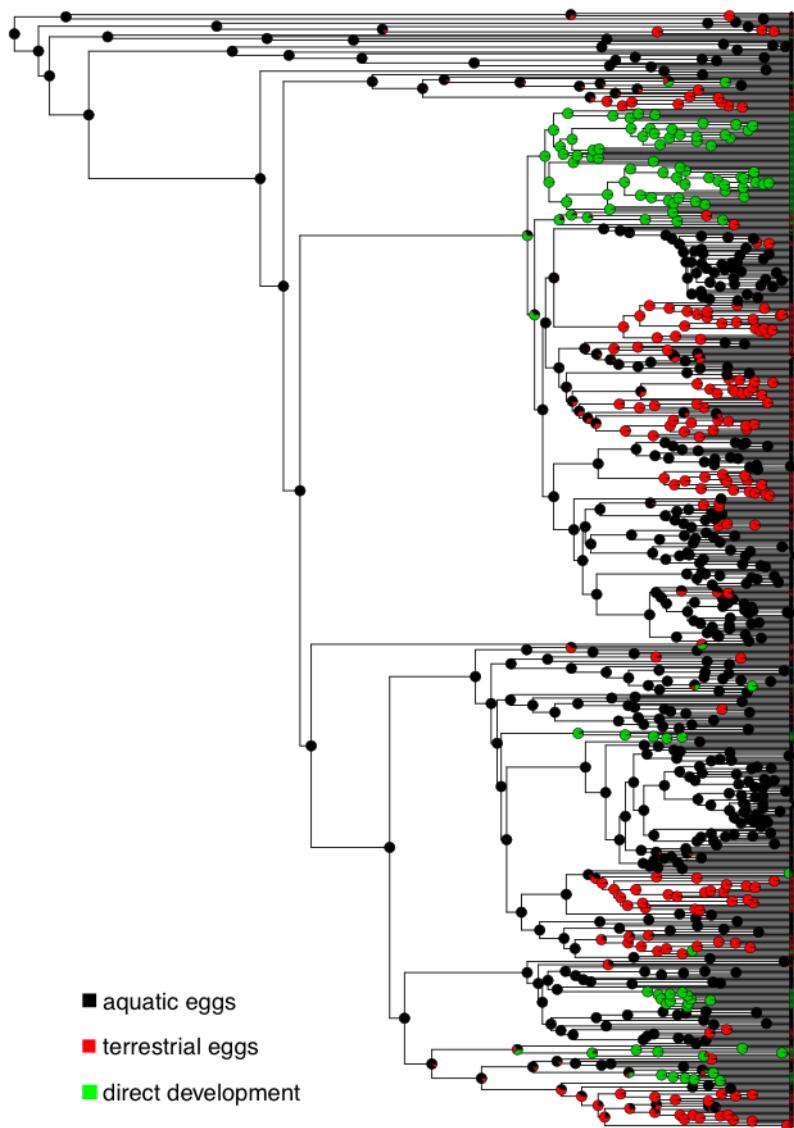

Figure 9.2. Ancestral state reconstruction of frog reproductive modes.
Data from Gomez-Mestre et al. (2012)

sequence.

Unfortunately, when analyzing morphological character evolution, we are often interested in single characters, and the use of shared models across characters seems impossible to justify. There is usually no equivalence between different character states for different characters: an A is an A for sequences, but a “1” in a character matrix usually corresponds to the presence of two completely different characters. The consequence of this difference is reflected in the statistical property of multivariate data. For gene sequence problems, adding more data in the form of additional characters (sites) makes model-fitting easier, as each site adds information about the overall (shared) model across sites. With character data, additional characters do not make the problem any easier, because each character comes with its own model parameters. In fact, we will see that when considering character correlations using a generalized Mk model, adding characters actually makes the problem more and more difficult. Perhaps these issues partially explain the slow pace of model development for fitting discrete characters to trees. There are a few potential solutions, such as threshold models [Felsenstein (2005); Felsenstein (2012); discussed below]. More work is desperately needed in this area.

In this chapter, we will first discuss extensions of Mk models that allow us to add complexity to this simple model. We also discuss threshold models, a relatively new approach in comparative methods that is distinct from Mk models and has some potential for future development.

Section 9.3: Pagel’s λ , δ , and κ (lambda, delta, and kappa)

The three Pagel models discussed in chapter 6 (Pagel 1999a,b) can also be applied to discrete characters. We do not create a phylogenetic variance-covariance matrix for species under an Mk model, so these three models can, in this case, only be interpreted in terms of transformations of the tree’s branch lengths. However, the meaning of each parameter is the same as in the continuous case: λ scales the tree from its original form to a “star” phylogeny, and thus quantifies whether the data fits a tree-based model or one where all species are independent;

δ captures changes in the rate of trait evolution through time; and κ scales branch lengths between their original values and one, and mimics a speciation model of evolution (but only if all species are sampled and there has been no extinction).

Just as with discrete characters, the three Pagel models can be evaluated in either an ML / AIC_c framework or using Bayesian analysis. One might expect these models to behave differently when applied to discrete rather than continuous characters, though. The main reason for this is that discrete characters, when they evolve rapidly, lose historical information surprisingly quickly. That means that models with high rates of character transitions will be quite similar to both models with low “phylogenetic signal” (i.e. $\lambda = 0$) and with rates that accelerate through time (i.e. $\delta > 0$). This indicates potential problems with model identifiability, and warns us that we might not have good power to differentiate one model from another.

We can apply these three models to data on frog reproductive modes. But first, we should try the Mk and extended-Mk models. Doing so, we find the following results:

Model	lnL	AIC_c	ΔAIC_c	AIC Weight
ER	-316.0	633.9	38.0	0.00
SYM	-296.6	599.2	3.2	0.17
ARD	-291.9	596.0	0.0	0.83

We can interpret this as strong evidence against the ER model, with ARD as the best, and weak support in favor of ARD over SYM. We can then try the three Pagel parameters. Since the support for SYM and ARD were similar, we will add the extra parameters to each of them. Doing so, we obtain:

Model	Extra parameter	lnL	AIC_c	ΔAIC_c	AIC weight
ER		-316.0	633.9	38.0	0.00
ARD		-291.9	596.0	0	0.37
SYM	λ	-296.6	601.2	5.2	0.03
SYM	κ	-296.6	601.2	5.2	0.03

Model	Extra parameter	lnL	AIC_c	ΔAIC_c	AIC weight
SYM	δ	-295.6	599.2	3.2	0.07
ARD	λ	-292.1	598.3	2.3	0.11
ARD	κ	-291.3	596.9	0.9	0.24
ARD	δ	-292.4	599.0	3.0	0.08

Notice that our results are somewhat ambiguous, with AIC weights spread fairly evenly across the three Pagel models. Interestingly, the overall lowest AIC score (and the most AIC weight, though only just more than 1/3 of the total) is on the ARD model with no additional Pagel parameters. I interpret this to mean that, for these data, the standard ARD model with no alterations is probably a reasonable fit to the data compared to the Pagel-style alternatives considered above, especially given the additional complexity of interpreting tree transformations in terms of evolutionary processes.

Section 9.4: Mk models where parameters vary across clades and/or through time

Another generalization of the Mk model we might imagine is a Mk model where rate parameters vary, either across clades or through time. There is some recent work along these lines, with two approaches that consider the possibility that rates of evolution for an Mk model vary on different branches of a phylogenetic tree (Marazzi et al. 2012; Beaulieu et al. 2013).

We can understand how these methods work in general terms by considering a simple case where the rate of character evolution is faster in one clade than in the rest of the tree. This is the discrete-character version of the approaches for continuous characters that I discussed in chapter 6 (O’Meara et al. 2006b; Thomas et al. 2006). The simplest way to implement a multi-rate discrete model is to directly incorporate variation across models into the pruning algorithm that is used to calculate the Mk model on a phylogenetic tree (see FitzJohn 2012 for implementation).

One can, for example, consider a model where the overall rate of evolution varies between clades in a phylogenetic tree. To do this, we can specify the background rate of evolution using some transition matrix \mathbf{Q} , and then assume that within our focal clade evolution can be modeled with some scalar value r , such that the new rate matrix is $r\mathbf{Q}$. Given \mathbf{Q} and r , one can calculate the likelihood for this model using the pruning algorithm, modified in such a way that the appropriate transition matrix is used along each branch in the tree; one can then maximize the likelihood of the model for all parameters (those describing \mathbf{Q} , as well as r , which describes the relative rate of evolution in the focal clade compared to the background).

In even more general terms, we will consider the situation where we can describe the model of evolution using a set of \mathbf{Q} matrices: $\mathbf{Q}_1, \mathbf{Q}_2, \dots, \mathbf{Q}_n$, each of which can be assigned to a particular branch in a phylogenetic tree (or be assigned to branches depending on some other character that influences the rate of the focal character; Marazzi et al. 2012). The only limit here is that each \mathbf{Q} matrix adds a new set of model parameters that must be estimated from the data, and it is easy to imagine this model becoming overparametrized. If we imagine a model where every branch has its own \mathbf{Q} -matrix, then we are actually describing the “no common mechanism” model (Tuffley and Steel 1997; Steel and Penny 2000), which is statistically identical to parsimony. It should also be possible to create a method that explores all models connecting simple Mk and the no common mechanism model using the machinery of reversible-jump MCMC, although I do not think such an approach has ever been implemented (but see Huelsenbeck et al. 2004).

One can also describe a situation where rate parameters in the \mathbf{Q} matrix change through time. This might follow a constant pattern of increase or decrease through time, or might be related to some external driver like temperature. One can mimic models where rates change through time by changing the branch lengths of phylogenetic trees. If deep branches are lengthened relative to shallow branches, as is done by Pagel’s δ , then we can fit a model where rates of evolution slow through time; conversely, lengthening shallow branches relative to deep ones creates a model where the overall rate of evolution accelerates through time (see FitzJohn 2012).

More work could certainly be done in the area of time-varying rates of change. The most general approach is to write a set of differential equations that describe the changes in character state along single branches in the tree. Parameters in those equations can be made to vary, either through time or even in a way that is correlated with some external variable hypothesized to influence rates of change, like temperature or rainfall. Given such a model, the reverse-time approach of (Maddison et al. 2007) can then be used to fit general time-varying (or even clade-varying) Mk models to data (see Uyeda et al. 2016).

Section 9.5: Threshold models

Recently, Joe Felsenstein (2005, 2012) introduced a model from quantitative genetics, the threshold model, to comparative methods. Threshold models work by modeling a discrete character as underlain by some other, unobserved, continuous trait (called the liability). If the liability crosses a certain threshold value, then the discrete state changes. More specifically, we can consider a single trait, y , with two states, 0 and 1, which is in turn determined by some underlying continuous variable, x , called the liability. If x is greater than the threshold, t , then y is 1; otherwise, y is 0. Felsenstein (2005) assumes that x evolves under a Brownian motion model, although other models like OU are, in principle, possible.

We can find the likelihood to this model by considering the observations of character states at the tips of the tree. We observe the state of each species, y_i . We do not know the liability values for these species. However, we treat these liabilities as unobserved and consider their distributions. Under a Brownian motion model, we know that the liabilities will follow a multivariate normal distribution (see chapter 3). We can calculate the probability of observing the data (y_i) by finding the integral of the distributions of liabilities on the side of the threshold that matches the data. So if the distribution of the liability for species i is $p_i(x)$, then:

(eq 9.1)

$$p(y_i = 0) = \int_{-\infty}^t p_i(x)dx$$

and

$$p(y_i = 1) = \int_t^{\infty} p_i(x)dx$$

(see Figure 9.3 for an illustration of this calculation, which is easier than it looks since there are standard formulas for finding the area under a normal distribution).

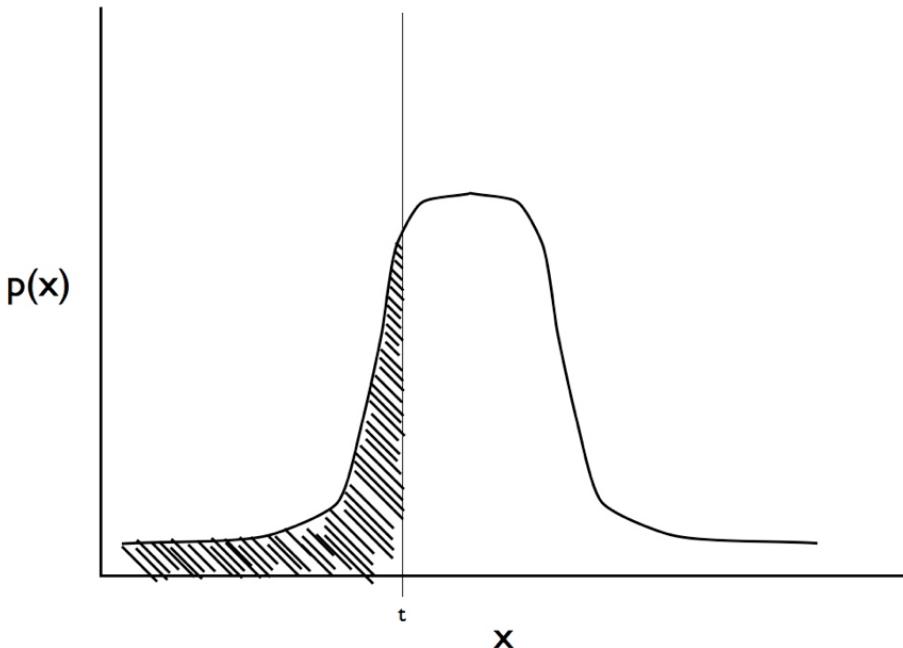

Figure 9.3. Illustration of the integral in equation 9.1. For a trait with observed state zero we calculate the area under the curve from negative infinity to the threshold t .

One can fit this model using standard ML or Bayesian methods. Current implementations include an expectation-maximization (EM) algo-

rithm (Felsenstein 2005, 2012) and a Bayesian MCMC (Revell 2014).

The threshold model differs in some key ways from standard Mk-type models. First of all, threshold characters evolve differently than non-threshold characters because of their underlying liability. In particular, the effective rate of change of the discrete character depends on the amount of time that a lineage has been in that character state. Characters that have just changed (say, from 0 to 1) are likely to change back (from 1 to 0), since the liability is likely to be near the threshold. By contrast, characters that have been in one state or the other for a long time tend to be more unlikely to change (since the liability is likely very far from the threshold). This difference matches biological intuition for some characters, where millions of years in one state means that change to a different state might be unlikely. This behavior of the threshold model can potentially account for variation in transition rates across clades without adding additional model parameters. Second, the threshold model scales to cover more than one character more readily than Mk models. Finally, in a threshold framework, it is straightforward to extend the model to include a mixture of both discrete and continuous characters – basically, one assumes that the continuous characters are like “observed liabilities,” and can be modeled together with the discrete characters.

Section 9.6: Modeling more than one discrete character at a time

It is extremely common to have datasets with more than one discrete character – in fact, one could argue that multivariate discrete datasets are the cornerstone of systematics. Nowadays, the most common multivariate discrete datasets are composed of genetic/genomic data. However, the foundations of modern phylogenetic comparative biology were laid out by Hennig (1999) and the other early cladists, who worked out methods for using discrete character data to obtain phylogenetic trees that show the evolutionary history of clades.

Almost all phylogenetic reconstruction methods that use discrete characters as data make a key assumption: that each of these characters

evolves independently from one another. Mathematically, one calculates the likelihood for each single character, then multiplies this likelihood (or, equivalently, adds the log-likelihood) across all characters to obtain the likelihood of the data.

The assumption of character independence is clearly not true in general. In the case of morphological characters, structures often interact with one another to determine the fitness of an individual, and it seems very likely that those structures are not independent. In fact, sometimes we are specifically interested in whether or not particular sets of characters evolve independently or not. Methods that assume character independence *a priori* are not useful for that sort of framework.

Felsenstein (1985) made a huge impact on the field of evolutionary biology with a statistical argument about species: species can not be considered independent data points because they share an evolutionary history. Species that are most closely related to one another will covary, simply due to that shared history. Nowadays, one cannot publish a paper in comparative biology without accounting directly for the non-independence of species that evolve on a tree. However, it is still very common to ignore the non-independence of characters, even when they occur together in the same organism! Surely the shared developmental history of two characters within one body commonly leads to correlations across these characters.

Section 9.7: Testing for correlated evolution of different characters

Hypotheses in evolutionary biology often relate to whether two (or more) traits evolve in a correlated manner (see Chapter 5). One can have a standard correlation between two discrete traits if knowing the state of one trait allows you to predict the state of the other. However, in evolution, these correlations will arise due to the shared patterns of relatedness across species. We are typically more interested in evolutionary correlations (see Chapter 5). With discrete traits, we can define evolutionary correlations in a specific way: two discrete traits share an evolutionary correlation if the state of one character affects the transition rates of a second.

Imagine that we are considering the evolution of two traits, trait 1 and trait 2, on a phylogenetic tree. Both traits have two possible character states, one and zero. We can show these two traits visually as Figure 9.4.

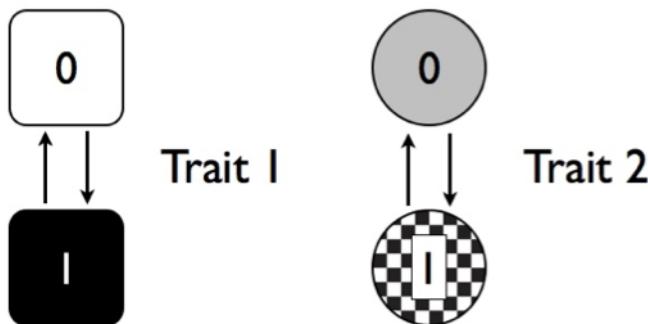

Figure 9.4. Two discrete character traits, each with two states (labeled 0 and 1).

In the figure, each trait has two possible transition rates, from 0 to 1 and from 1 to 0. For now, let's assume that backwards and forward rates are equal. Any species can have one of four possible combinations of the two traits (00, 01, 10, or 11). We can draw the transitions among these four combinations as Figure 9.5.

In Figure 9.6, I have marked the distinct rates with different rectangles – black represents changes in trait 1, while checkered is changes in trait 2. Notice that, in this figure, we are assuming that the two traits are independent. That is, in this model the transition rates of trait one do not depend on the state of trait 2, and vice-versa. What would happen to our model if we allow the traits to evolve in a dependent manner?

Notice that in Figure 9.6, we have four different transition rates. Consider first the solid rectangles. The grey rectangle represents the transition rate for trait 1 when trait 2 has state 0, while the black rectangle represents the transition rate for trait 1 when trait 2 has state 1. If these two rates are different, then the traits are dependent on each other – that is, the rate of evolution of trait 1 depends on the character state of trait 2.

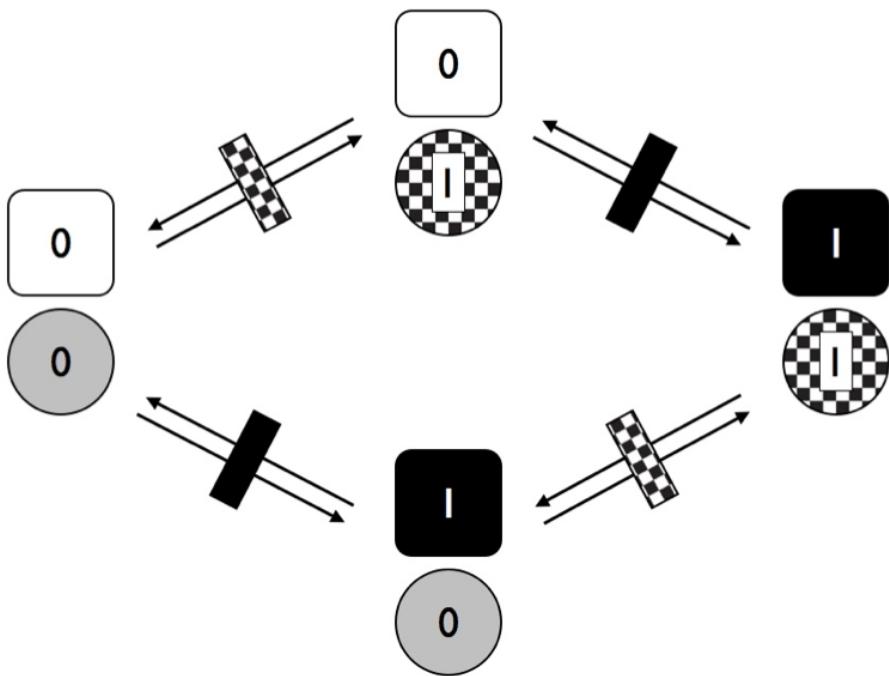

Figure 9.5. Transitions among states for two traits with two character states each where characters evolve independently of one another.

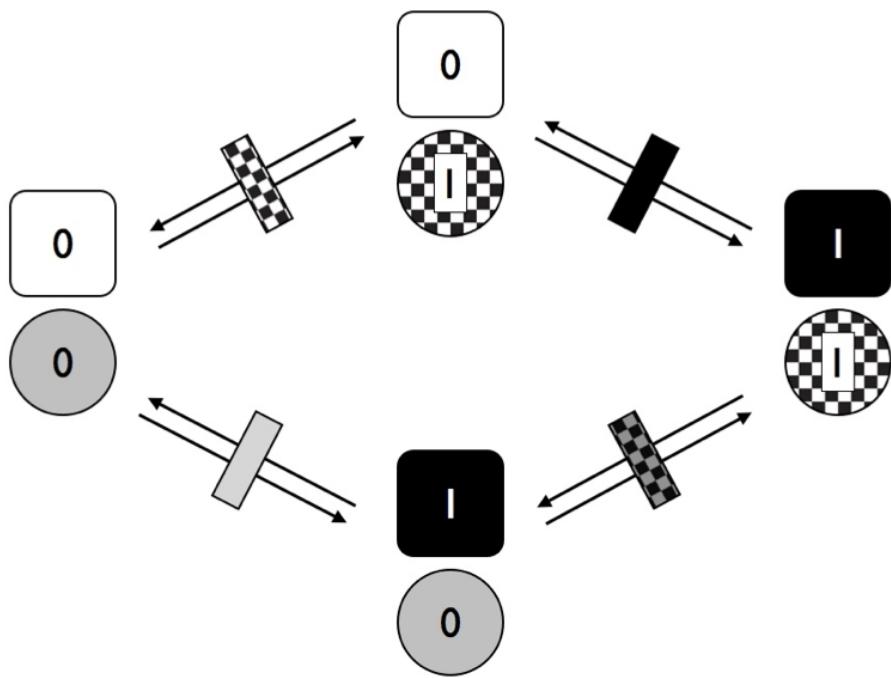

Figure 9.6. Transitions among states for two traits with two character states each where characters evolve at rates that depend on the character state of the other trait.

These two models have different numbers of parameters, but are relatively easy to fit using the maximum-likelihood approach outlined in this chapter. The key is to write down the transition matrix (\mathbf{Q}) for each model. For example, a transition matrix for model in figure 9.4 is:

(eq. 9.2)

$$\mathbf{Q} = \begin{bmatrix} -q_1 - q_2 & q_1 & q_2 & 0 \\ q_1 & -q_1 - q_2 & 0 & q_2 \\ q_2 & 0 & -q_1 - q_2 & q_1 \\ 0 & q_2 & q_1 & -q_1 - q_2 \end{bmatrix}$$

In the matrix above, each row and column corresponds to a particular combination of states for character 1 and 2: (0,0), (0,1), (1,0), and (1,1). Note that some possible transitions in this model have rate 0, meaning they do not occur. These are transitions that would require both characters to change exactly simultaneously (e.g. (0,0) to (1,1) – a possibility that is excluded from this model).

Similarly, we can write a transition matrix for the model in figure 9.5:

(eq. 9.3)

$$\mathbf{Q} = \begin{bmatrix} -q_1 - q_2 & q_1 & q_2 & 0 \\ q_1 & -q_1 - q_3 & 0 & q_3 \\ q_2 & 0 & -q_2 - q_4 & q_4 \\ 0 & q_3 & q_4 & -q_3 - q_4 \end{bmatrix}$$

Notice that the simple, 2-parameter independent evolution model is a special case of the more complex, 4-parameter dependent model. Because of this, we can compare the two with a likelihood ratio test. Alternatively, AIC or Bayes factors can be used. If we find support for the 4-parameter model, we can conclude that the two characters have an evolutionary correlation.

It is worth noting that there are other models that one can fit for the evolution of two binary traits that I did not discuss above. For example, one can model the situation where the two traits each have different forwards and backwards rates, but are evolving independently. This

is a four-parameter model. Additionally, one can allow both forward and backward rates to differ and to depend on the character state of the other trait: an eight-parameter model. All of these models – and others not described here – can be compared using AIC, BIC, or Bayes Factors. Pagel and Meade (2006) describe a particularly innovative and synthetic method to test hypotheses about correlated evolution of discrete characters in a Bayesian framework using reversible-jump MCMC.

One can also test for correlations among discrete characters using threshold models. Here, one tests whether or not the liabilities for the two characters evolve in a correlated fashion. More specifically, we can model liabilities for the two threshold characters using a bivariate Brownian motion model, with some evolutionary covariance σ_{12}^2 between the two liabilities. We can then use either ML or Bayesian methods to determine if the evolutionary covariance between the two characters is non-zero (following the methods described in chapter 5, but using likelihoods based on discrete characters as described above).

Section 9.8: Chapter summary

The simple Mk model provides a useful foundation for a number of innovative methods. These methods capture evolutionary processes that are more complicated than the original model, including models that vary through time or across clades. Modeling more than one discrete character at a time allows us to test for the correlated evolution of discrete characters.

Taken as a whole, chapters 7 through 9 provide a basis for the analysis of discrete characters on trees. One can test a variety of biologically relevant hypotheses about how these characters have changed along the branches of the tree of life.

Chapter 10: Introduction to birth-death models

Section 10.1: Plant diversity imbalance

The diversity of flowering plants (the angiosperms) dwarfs the number of species of their closest evolutionary relatives (Figure 10.1). There are more than 260,000 species of angiosperms (that we know; more are added every day). The clade originated more than 140 million years ago (Bell et al. 2005), and all of these species have formed since then. One can contrast the diversity of angiosperms with the diversity of other groups that originated at around the same time. For example, gymnosperms, which are as old as angiosperms, include only around 1000 species, and may even represent more than one clade. The diversity of angiosperms also dwarfs the diversity of familiar vertebrate groups of similar age (e.g. squamates - snakes and lizards - which diverged from their sister taxon, the tuatara, some 250 mya or more Hedges et al. 2006, include fewer than 8000 species).

The evolutionary rise of angiosperm diversity puzzled Darwin over his career, and the issues surrounding angiosperm diversification are often referred to as “Darwin’s abominable mystery” in the scientific literature (e.g. Davies et al. 2004). The main mystery is the tremendous variation in numbers of species across plant clades (see Figure 10.1). This variation even applies within angiosperms, where some clades are much more diverse than others.

At a global scale, the number of species in a clade can change only via two processes: speciation and extinction. This means that we must look to speciation and extinction rates – and how they vary through time and across clades – to explain phenomena like the extraordinary diversity of Angiosperms. It is to this topic that we turn in the next few chapters. Since Darwin’s time, we have learned a lot about the evolutionary processes that led to the diversity of angiosperms that we see today. These data provide an incredible window into the causes and effects of speciation and extinction over macroevolutionary time scales.

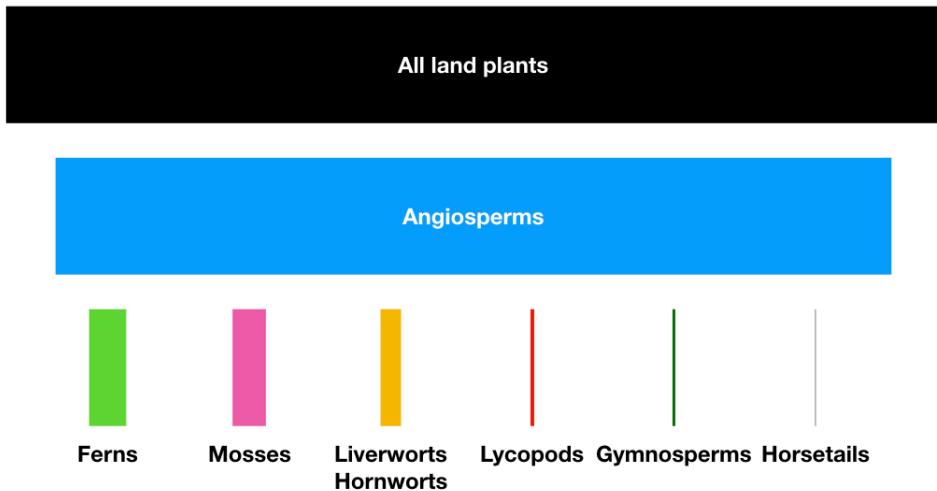

Figure 10.1. Diversity of major groups of embryophytes (land plants); bar areas are proportional to species diversity of each clade. Angiosperms, including some 250,000 species, comprise more than 90% of species of land plants. Figure modified from Crepet and Niklas (2009)

Comparative methods can be applied to understand patterns of species richness by estimating speciation and extinction rates, both across clades and through time. In this chapter, I will introduce birth-death models, by far the most common model for understanding diversification in a comparative framework. I will discuss the mathematics of birth-death models and how these models relate to the shapes of phylogenetic trees. I will describe how to simulate phylogenetic trees under a birth-death model. Finally, I will discuss tree balance and lineage-through-time plots, two common ways to measure the shapes of phylogenetic trees.

Section 10.2: The birth-death model

A birth-death model is a continuous-time Markov process that is often used to study how the number of individuals in a population change through time. For macroevolution, these “individuals” are usually species, sometimes called “lineages” in the literature. In a birth-death model, two things can occur: births, where the number of individuals increases by one; and deaths, where the number of individuals decreases by one. We assume that no more than one new individual can form (or die) during any one event. In phylogenetic terms, that means that birth-death trees cannot have “hard polytomies” - each speciation event results in exactly two descendant species.

In macroevolution, we apply the birth-death model to species, and typically consider a model where each species has a constant probability of either giving birth (speciating) or dying (going extinct). We denote the per-lineage birth rate as λ and the per-lineage death rate as μ . For now we consider these rates to be constant, but we will relax that assumption later in the book.

We can understand the behavior of birth-death models if we consider the waiting time between successive speciation and extinction events in the tree. Imagine that we are considering a single lineage that exists at time t_0 . We can think about the waiting time to the next event, which will either be a speciation event splitting that lineage into two (Figure 10.2A) or an extinction event marking the end of that lineage (Figure 10.2B). Under a birth-death model, both of these events follow

a Poisson process, so that the expected waiting time to an event follows an exponential distribution (Figure 10.2C). The expected waiting time to the next speciation event is exponential with parameter λ , and the expected waiting time to the next extinction event exponential with parameter μ . [Of course, only one of these can be the next event. The expected waiting time to the next event (of any sort) is exponential with parameter $\lambda + \mu$, and the probability that that event is speciation is $\lambda/(\mu + \lambda)$, extinction $\mu/(\mu + \lambda)$].

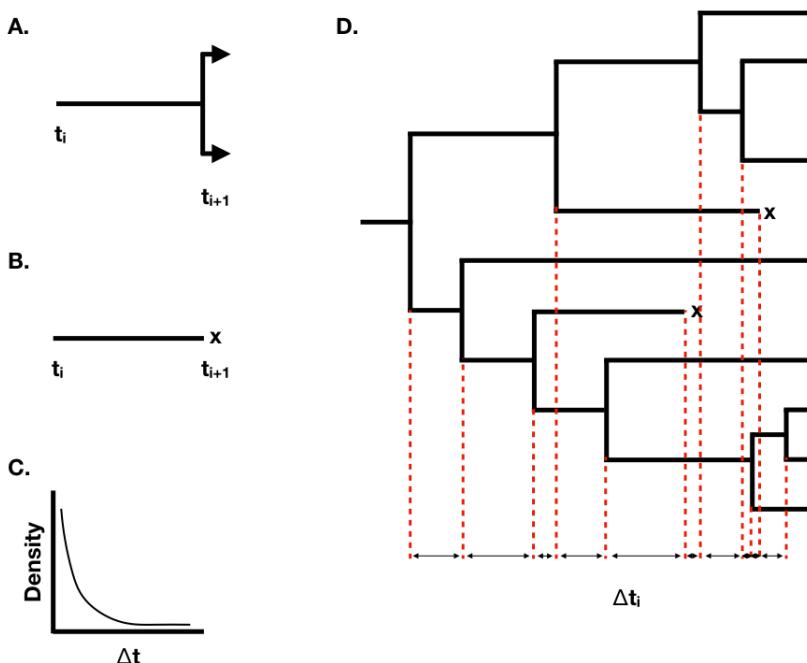

Figure 10.2. Illustration of the basic properties of birth-death models. A. Waiting time to a speciation event; B. Waiting time to an extinction event; C. Exponential distribution of waiting times until the next event; D. A birth-death tree with waiting times, with x denoting extinct taxa.

When we have more than one lineage “alive” in the tree at any time point, then the waiting time to the next event changes, although its distribution is still exponential. In general, if there are $N(t)$ lineages alive at time t , then the waiting time to the next event follows an exponential distribution with parameter $N(t)(\lambda + \mu)$, with the probability

that that event is speciation or extinction the same as given above. You can see from this equation that the rate parameter of the exponential distribution gets larger as the number of lineages increases. This means that the expected waiting times across all lineages get shorter and shorter as more lineages accumulate.

Using this approach, we can grow phylogenetic trees of any size (Figure 10.2D).

We can derive some important properties of the birth-death process on trees. To do so, it is useful to define two additional parameters, the net diversification rate (r) and the relative extinction rate (ϵ):

(eq. 10.1)

$$r = \lambda - \mu$$

These two parameters simplify some of the equations below, and are also commonly encountered in the literature.

To derive some general properties of the birth-death model, we first consider the process over a small interval of time, Δt . We assume that this interval is so short that it contains at most a single event, either speciation or extinction (the interval might also contain no events at all). The probability of speciation and extinction over the time interval can be expressed as:

(eq. 10.2)

$$Pr_{speciation} = N(t)\lambda\Delta t$$

$$Pr_{extinction} = N(t)\mu\Delta t$$

We now consider the total number of living species at some time t , and write this as $N(t)$. It is useful to think about the expected value of $N(t)$ under a birth-death model [we consider the full distribution of $N(t)$ below]. The expected value of $N(t)$ after a small time interval Δt is:

(eq. 10.3)

$$N(t + \Delta t) = N(t) + N(t)\lambda\Delta t - N(t)\mu\Delta t$$

We can convert this to a differential equation by subtracting $N(t)$ from both sides, then dividing by Δt and taking the limit as Δt becomes very small:

(eq. 10.4)

$$dN/dt = N(\lambda - \mu)$$

We can solve this differential equation if we set a boundary condition that $N(0) = n_0$; that is, at time 0, we start out with n_0 lineages. We then obtain:

(eq. 10.5)

$$N(t) = n_0 e^{\lambda - \mu} t = n_0 e^{rt}$$

This deterministic equation gives us the expected value for the number of species through time under a birth-death model. Notice that the number of species grows exponentially through time as long as $\lambda > \mu$, e.g. $r > 0$, and decays otherwise (Figure 10.3).

We are also interested in the stochastic behavior of the model – that is, how much should we expect $N(t)$ to vary from one replicate to the next? We can calculate the full probability distribution for $N(t)$, which we write as $p_n(t) = \Pr[N(t) = n]$ for all $n \geq 0$, to completely describe the birth-death model's behavior. To derive this probability distribution, we can start with a set of equations, one for each value of n , to keep track of the probabilities of n lineages alive at time t . We will denote each of these as $p_n(t)$ (there are an infinite set of such equations, from p_0 to p_∞). We can then write a set of difference equations that describe the different ways that one can reach any state over some small time interval Δt . We again assume that Δt is sufficiently small that at most one event (a birth or a death) can occur. As an example, consider what can happen to make $n = 0$ at the end of a certain time interval. There are two possibilities: either we were already at $n = 0$ at the beginning of the time interval and (by definition) nothing happened, or we were at $n = 1$ and the last surviving lineage went extinct. We write this as:

(eq. 10.6)

$$p_0(t + \Delta t) = p_1(t)\mu\Delta t + p_0(t)$$

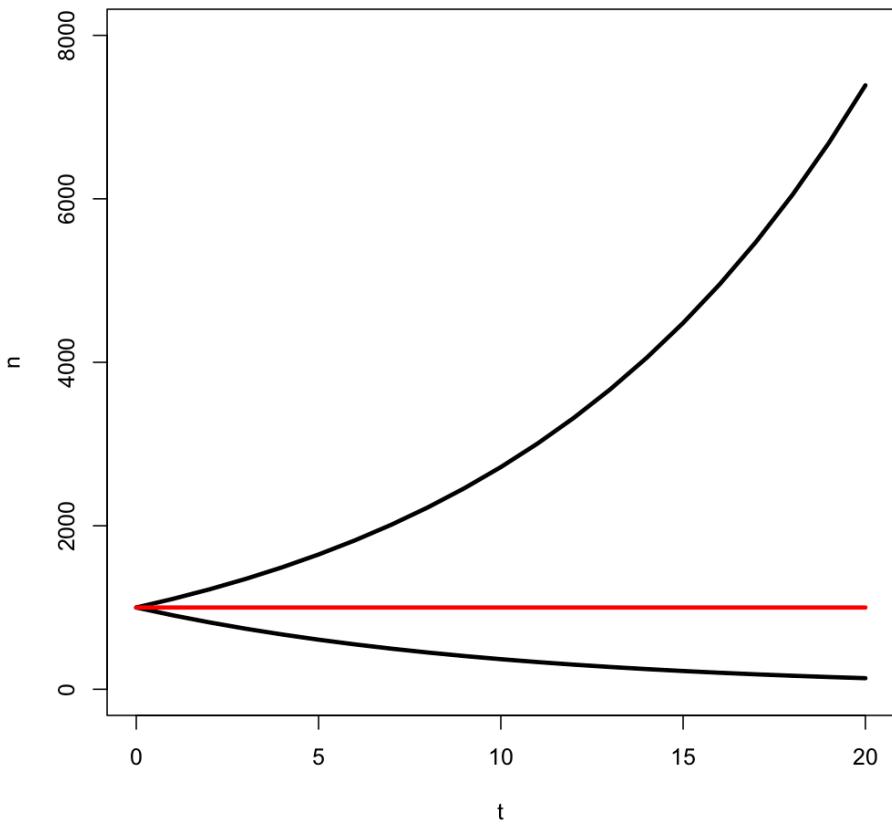

Figure 10.3. Expected number of species under a birth-death model with $r = \lambda - \mu > 0$ (top line), $r = 0$ (middle line), and $r < 0$ (bottom line). In each case the starting number of species was $n_0 = 1000$.

Similarly, we can reach $n = 1$ by either starting with $n = 1$ and having no events, or going from $n = 2$ via extinction.

(eq. 10.7)

$$p_1(t + \Delta t) = p_1(t)(1 - (\lambda + \mu))\Delta t + p_2(t)2\mu\Delta t$$

Finally, any $n > 1$, we can reach the state of n lineages in three ways: from a birth (from $n - 1$ to n), a death (from $n + 1$ to n), or neither (from n to n).

(eq. 10.8)

$$p_n(t + \Delta t) = p_{n-1}(t)(n-1)\lambda\Delta t + p_{n+1}(t)(n+1)\mu\Delta t + p_n(t)(1 - n(\lambda + \mu))\Delta t$$

We can convert this set of difference equations to differential equations by subtracting $p_n(t)$ from both sides, then dividing by Δt and taking the limit as Δt becomes very small. So, when $n = 0$, we use 10.6 to obtain:

(eq. 10.9)

$$dp_0(t)/dt = \mu p_1(t)$$

From 10.7:

(eq. 10.10)

$$dp_1(t)/dt = 2\mu p_2(t) - (\lambda - \mu)p_1(t)$$

and from 10.8, for all $n > 1$:

(eq. 10.11)

$$dp_n(t)/dt = (n - 1)\lambda p_{n-1}(t) + (n + 1)\mu p_{n+1}(t) - n(\lambda + \mu)p_n(t)$$

We can then solve this set of differential equations to obtain the probability distribution of $p_n(t)$. Using the same boundary condition, $N(0) = n_0$, we have $p_0(t) = 1$ for $n = n_0$ and 0 otherwise. Then, we can find the solution to the differential equations 10.9, 10.10, and 10.11. The derivation of the solution to this set of differential equations is beyond the scope of this book (but see Kot 2001 for a nice explanation of the

mathematics). A solution was first obtained by Bailey (1964), but I will use the simpler equivalent form from Foote et al. (1999). For $p_0(t)$ – that is, the probability that the entire lineage has gone extinct at time t – we have:

(eq. 10.12)

$$p_0(t) = \alpha_0^n$$

And for all $n \geq 1$:

(eq. 10.13)

$$p_n(t) = \sum_{j=1}^{\min(n_0, n)} \binom{n_0}{j} \binom{n-1}{j-1} \alpha^{n_0-j} \beta^{n-j} [(1-\alpha)(1-\beta)]^j$$

Where α and β are defined as:

(eq. 10.14)

$$\begin{aligned} \alpha &= \frac{\epsilon(e^r t - 1)}{(e^r t - \epsilon)} \\ \beta &= \frac{(e^r t - 1)}{(e^r t - \epsilon)} \end{aligned}$$

α is the probability that any particular lineage has gone extinct before time t .

Note that when $n_0 = 1$ – that is, when we start with a single lineage – equations 10.12 and 10.13 simplify to (Raup 1985):

(eq. 10.15)

$$p_0(t) = \alpha$$

And for all $n \geq 1$:

(eq. 10.16)

$$p_n(t) = (1-\alpha)(1-\beta)\beta^{i-1}$$

In all cases the expected number of lineages in the tree is exactly as stated above in equation (10.5), but now we have the full probability distribution of the number of lineages given n_0 , t , λ , and μ . A few plots capture the general shape of this distribution (Figure 10.4).

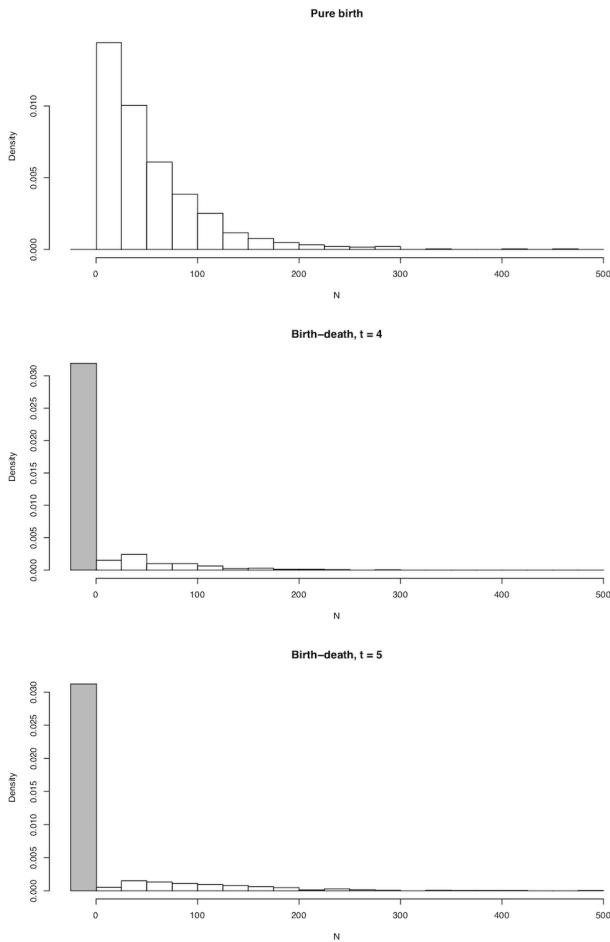

Figure 10.4. Probability distributions of $N(t)$ under A. pure birth, B. birth death after a short time, and C. birth-death after a long time.

There are quite a few comparative methods that use clade species richness and age along with the distribution defined in 10.14 and 10.15 to make inferences about clade diversification rates (see chapter 11).

Section 10.3: Birth-death models and phylogenetic trees

The above discussion considered the number of lineages under a birth-death model, but not their phylogenetic relationships. However, just by keeping track of the parent-offspring relationships among lineages, we can consider birth-death models that result in phylogenetic trees (e.g. Figure 10.2D).

The main complication in phylogenetic studies of birth-death models is that we get a “censored” view of the process, in that we only observe lineages that survive to the present day. In the above example, if the true phylogenetic tree were the one plotted in 10.5A, we would only have a chance to observe the phylogenetic tree in figure 10.5B – and even then only if we sampled all of the species and reconstructed the tree with perfect accuracy! A partially sampled tree with only extant species can be seen in Figure 10.5C. I will cover the relationship between birth-death models and the branch lengths of phylogenetic trees in much more detail in the next chapter.

Section 10.4: Simulating birth-death trees

We can use the statistical properties of birth-death models to simulate phylogenetic trees through time. We could begin with a single lineage at time 0. However, phylogenetic tree often start with the first speciation event in the clade, so one can also begin the simulation with two lineages at time 0 (this distinction relates to our earlier discussion of crown versus stem ages; see also Chapter 11).

To simulate our tree, we need to draw waiting times between speciation and extinction events, connect new lineages to the tree, and prune lineages when they go extinct. We also need a stopping criterion, which can have to do with a particular number of taxa or a fixed time interval.

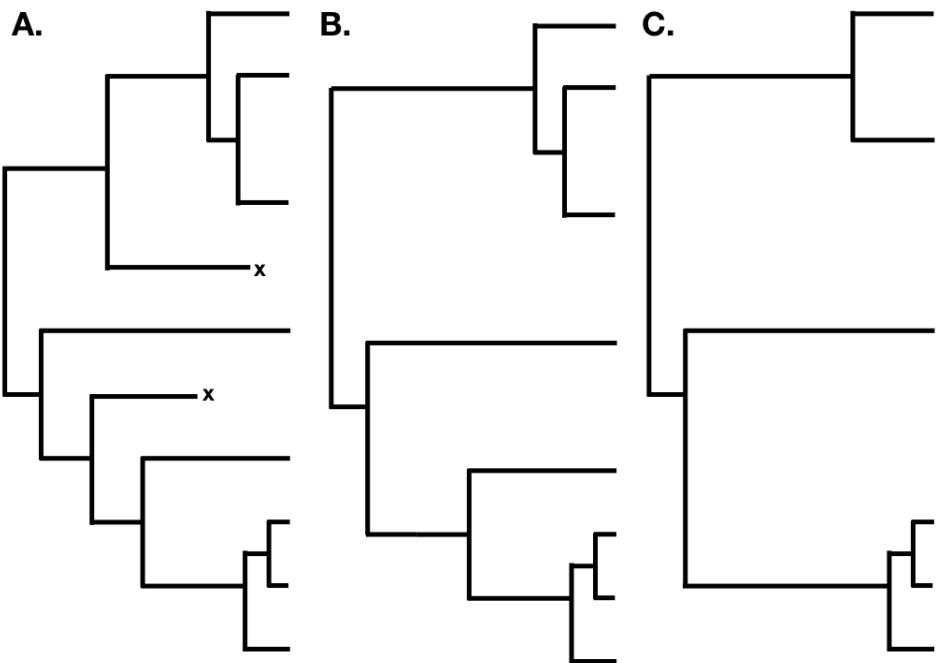

Figure 10.5. A. A birth-death tree including all extinct and extant species; B. A birth-death tree including only extant species; and C. A partially sampled birth-death tree including only some extant species.

We will consider the latter, and leave growing trees to a fixed number of taxa as an exercise for the reader. Our simulation algorithm is as follows. I assume that we have a certain number of “living” lineages in our tree (1 or 2 initially), a current time ($t_c = 0$ initially), and a stopping time t_{stop} .

1. Draw a waiting time t_i to the next speciation or extinction event. Waiting times are drawn from an exponential distribution with rate parameter $N_{alive} * (\lambda + \mu)$ where N_{alive} is the current number of living lineages in the tree.
2. Check to see if the simulation ends before the next event. That is, if $t_c + t_i > t_{stop}$, end the simulation.
3. Decide whether the next event is a speciation event [with probability $\lambda / (\lambda + \mu)$] or an extinction event [with probability $\mu / (\lambda + \mu)$]. This can be done by drawing a uniform random number u_i from the interval $[0, 1]$ and assigning speciation to the event if $u_i < \lambda / (\lambda + \mu)$ and extinction otherwise.
4. If (3) is a speciation event, then choose a random living lineage in the tree. Attach a new branch to the tree at this point, and add one new living lineage to the simulation. Return to step 1.
5. If (3) is an extinction event, choose a random living lineage in the tree. That lineage is now dead. As long as there is still at least one living lineage in the tree, return to (1); otherwise, your whole clade has gone extinct, and you can stop the simulation.

This procedure returns a phylogenetic tree that includes both living and dead lineages. One can prune out any extinct taxa to return a birth-death tree of survivors, which is more in line with what we typically study using extant species. It is also worth noting that entire clades can – and often do – go extinct under this protocol before one reaches time t_{stop} . Note also that there is a much more efficient way to simulate trees (Stadler 2011).

We can think about phylogenetic predictions of birth-death models in two ways: by considering tree topology, and by considering tree branch lengths. I will consider each of these two aspects of trees below.

Section 10.5: Tree topology, tree shape, and tree balance under a birth-death model

Tree topology summarizes the patterns of evolutionary relatedness among a group of species independent of the branch lengths of a phylogenetic tree. Two different trees have the same topology if they define the exact same set of clades. This is important because sometimes two trees can look very different and yet still have the same topology (e.g. Figure 10.6 A, B, and C).

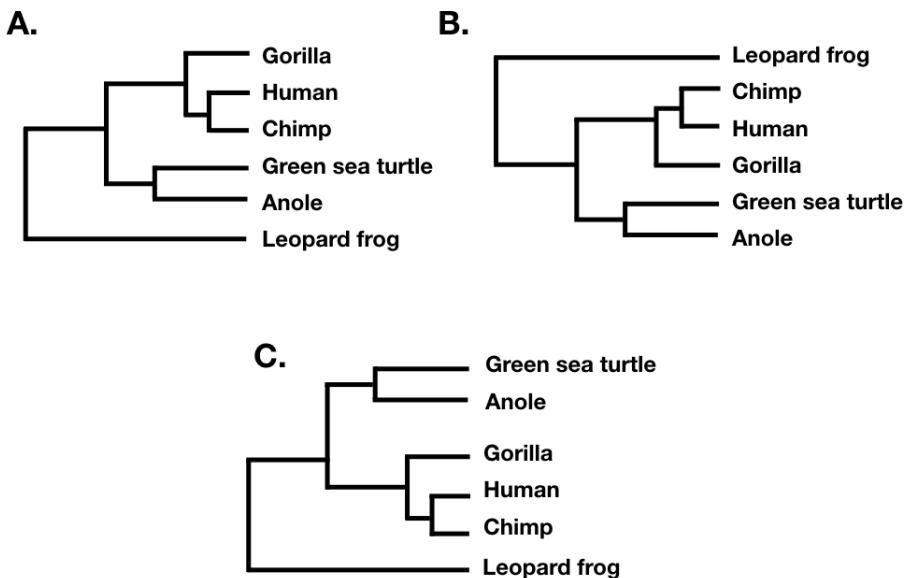

Figure 10.6. Several phylogenetic trees showing different ways to plot the same tree topology.

Tree shape ignores both branch lengths and tree tip labels. For example, the two trees in figure 10.7 A and B have the same tree shape even though they share no tips in common. What they do share is that their nodes have the same patterns in terms of the number of descendants on each “side” of the bifurcation. By contrast, the phylogenetic tree in

10.7 C has a different shape. (Note that what I am calling tree shape is sometimes referred to as “unlabeled” tree topology; e.g. Felsenstein 2004).

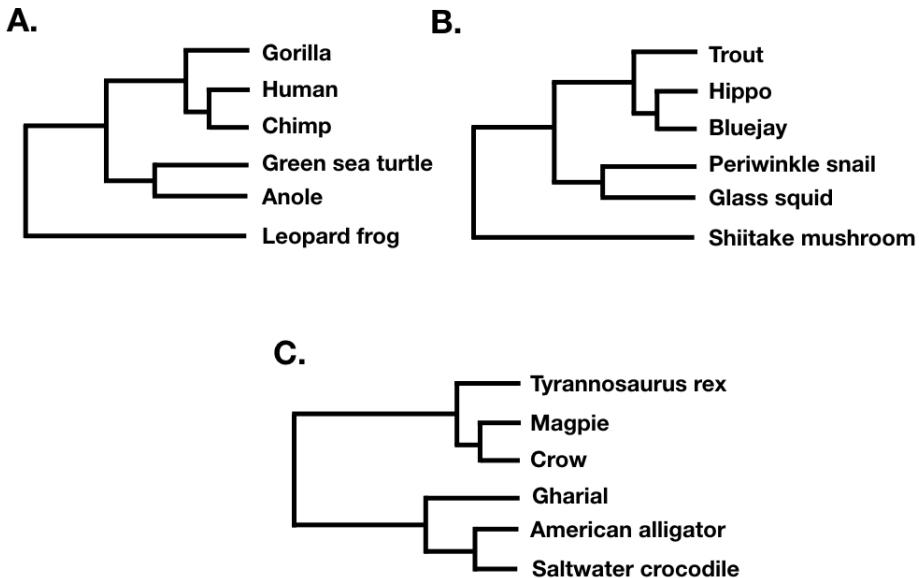

Figure 10.7. Two different phylogenetic trees sharing the same tree shape (A and B), and one with a different shape (C).

Finally, tree balance is a way of expressing differences in the number of descendants between pairs of sister lineages at different points in a phylogenetic tree. For example, consider the phylogenetic tree depicted in figure 10.7B. The deepest split in that tree separates a clade with five species (trout, hippo, bluejay, periwinkle snail, glass squid) from a clade with a single species (Shiitake mushroom), and so that node in the tree is unbalanced with a (5, 1) pattern. By contrast, the deepest split in 10.7C separates two clades of equal size. In that tree, the deepest node is balanced with a (3, 3) pattern. A number of approaches in macroevolution use balance at nodes and across whole trees to try to capture important evolutionary patterns.

We can start to understand these approaches by considering the balance of a single node n in a phylogenetic tree. There are two clades descended from this node; let's call them a and b . We assume that the total number of species descended from the node $N_{total} = N_a + N_b$ is constant and that neither N_a nor N_b is zero. An important result, first discussed by Farris (1976) for a pure-birth model, is that all possible numerical divisions of N_{total} into $N_a + N_b$ are equally probable. For example, if $N_{total} = 10$, then all possible divisions: 1 + 9, 2 + 8, 3 + 7, 4 + 6, 5 + 5, 6 + 4, 7 + 3, 8 + 2, and 9 + 1 are all equally probable, so that each will be predicted to occur with a probability 1/9. Formally,

(eq. 10.17)

$$p(N_a \mid N_{total}) = \frac{1}{N_{total} - 1}$$

Note that there is a subtle difference between equation 10.2 above and some equations in the literature, e.g. Slowinski and Guyer (1993). This difference has to do with whether we label the two descendent clades, a and b , or not; if the clades are unlabeled, then there is no difference between 4+6 and 6+4, so that the probability that the largest clade, whichever it might be, has 6 species is twice what is given by my equation.

Equation 10.17 applies even if there is extinction, as long as both sister clades have the same speciation and extinction rates (Slowinski and Guyer 1993). This equation has been used to compare diversification rates between sister clades, either for a single pair or across multiple pairs (see Chapter 11).

Tree balance statistics provide a way of comparing numbers of taxa across all of the nodes in a phylogenetic tree simultaneously. There are a surprisingly large number of tree balance statistics, but all rely on summarizing information about the balance of each node across a whole tree. Colless' index I_c (Colless 1982) is one of the simplest – and, perhaps, most commonly used – indices of tree balance. I_c is the sum of the difference in the number of tips subtended on each side of every node in the tree, standardized by the maximum that such a sum can achieve:

(eq. 10.18)

$$I_C = \frac{\sum_{all\ nodes} (N_L - N_R)}{(N - 1)(N - 2)/2}$$

If the tree is perfectly balanced (only possible when N is some power of 2, e.g. 2, 4, 8, 16, etc.), then $I_C = 0$ (Figure 10.7C). By contrast, if the tree is completely pectinate, which means that each split in the tree contrasts a clade with 1 species with the rest of the species in the clade, then $I_C = 1$ (Figure 10.7A). Most phylogenetic trees have values of I_C between 0 and 1 (Figure 10.7B).

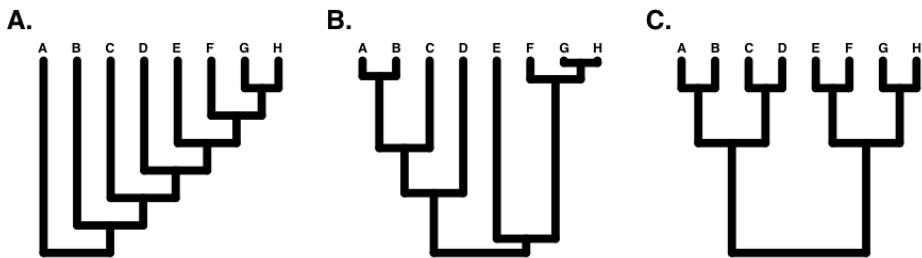

Figure 10.8. A. a pectinate tree ($I_C = 1$); B. a random tree ($0 < I_C < 1$); C. A balanced tree ($I_C = 0$).

There are a number of other indices of phylogenetic tree balance (re-reviewed in Mooers and Heard 1997). All of these indices are used in a similar way: one can then compare the value of the tree index to what one might expect under a particular model of diversification, typically birth-death. In fact, since these indices focus on tree topology and ignore branch lengths, one can actually consider their general behavior under a set of equal-rates Markov (ERM) models. This set includes any model where birth and death rates are equal across all lineages in a phylogenetic tree at a particular time. ERM models include birth-death models as described above, but also encompass models where birth and/or death rates change through time.

Section 10.6: Lineage-through-time plots

The other main way to quantify phylogenetic tree shape is by making lineage-through-time plots. These plots have time along the x axis (from the root of the tree to the present day), and the reconstructed number of lineages on the y-axis (Figure 10.8). Since we are usually considering birth-death models, where the number of lineages is expected to grow (or shrink) exponentially through time, then it is typical practice to log-transform the y-axis.

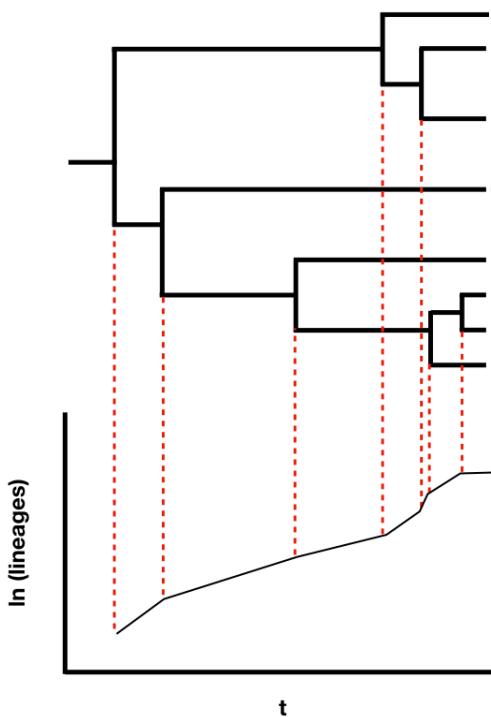

Figure 10.9. Lineage-through-time plot.

Lineage-through-time plots are effective ways to visualize patterns of lineage diversification through time. Under a pure-birth model, LTT plots follow a straight line on average (Figure 10.9A). By contrast, extinction should leave a clear signal in LTT plots because the probability of a lineage going extinct depends on how long it has been around; old lineages are much more likely to have been hit by extinction than relatively young lineages. We see this reflected in LTT plots as the “pull of

the present” – an upturn in the slope of the LTT plot near the present day (Figure 10.9B). Incomplete sampling – that is, not sampling all of the living species in a clade – can also have a huge impact on the shape of LTT plots (Figure 10.9C). We will discuss LTT plots further in chapter 11, where we will use them to make inferences about patterns of lineage diversification through time.

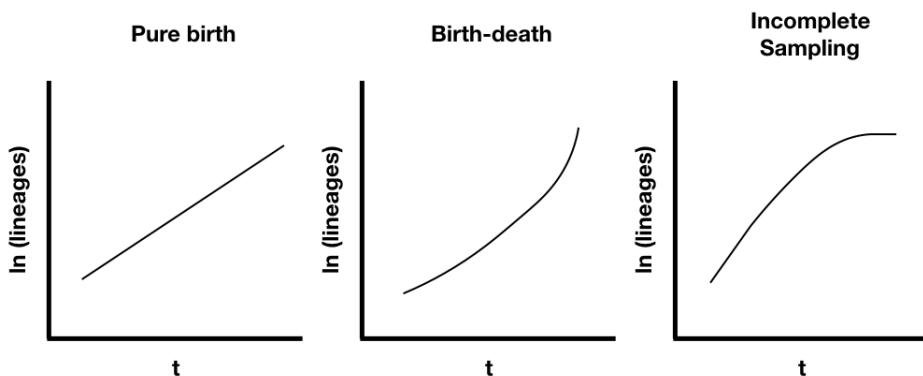

Figure 10.10. Example lineage-through-time plots.

Section 10.7: Chapter Summary

In this chapter, I introduced birth-death models and summarized their basic mathematical properties. Birth-death models predict patterns of species diversity over time intervals, and can also be used to model the growth of phylogenetic trees. We can visualize these patterns by measuring tree balance and creating lineage-through-time (LTT) plots.

Chapter 11: Fitting birth-death models

Section 11.1: Hotspots of diversity

The number of species on the Earth remains highly uncertain, but our best estimates are around 10 million (Mora et al. 2011). This is a mind-boggling number, and far more than have been described. As far as we know, all of those species are descended from a single common ancestor that lived some 4.2 billion years ago (Hedges and Kumar 2009). All of these species formed by the process of speciation, the process by which one species splits into two (or more) descendants (Coyne and Orr 2004).

Some parts of the tree of life have more species than others. This imbalance in diversity tells us that speciation is much more common in some lineages than others (Mooers and Heard 1997). Likewise, numerous studies have argued that certain habitats are “hotbeds” of speciation (e.g. Hutter et al. 2017; Miller and Wiens 2017). For example, the high Andes ecosystem called the Páramo - a peculiar landscape of alien-looking plants and spectacled bears - might harbor the highest speciation rates on the planet (Madriñán et al. 2013).

In this chapter we will explore how we can learn about speciation and extinction rates from the tree of life. We will use birth-death models, simple models of how species form and go extinct through time. Birth-death models can be applied to data on clade ages and diversities, or fit to the branching times in phylogenetic trees. We will explore both maximum likelihood and Bayesian methods to do both of these things.

Section 11.2: Clade age and diversity

If we know the age of a clade and its current diversity, then we can calculate the net diversification rate for that clade. Before presenting equations, I want to make a distinction between two different ways that one can measure the age of a clade: the stem age and the crown age. A clade’s crown age is the age of the common ancestor of all species in the clade. By contrast, a clade’s stem age measures the time that that

Figure 11.1 Páramo ecosystem, Chingaza Natural National Park, Colombia. Photo taken by the author.

clade descended from a common ancestor with its sister clade. The stem age of a clade is always at least as old, and usually older, than the crown age.

Magallón and Sanderson (2001) give an equation for the estimate of net diversification rate given clade age and diversity:

(eq. 11.1)

$$\hat{r} = \frac{\ln(n)}{t_{stem}}$$

where n is the number of species in the clade at the present day and t_{stem} is the stem group age. In this equation we also see the net diversification rate parameter, $r = \lambda - \mu$ (see Chapter 10). This is a good reminder that this parameter best predicts how species accumulate through time and reflects the balance between speciation and extinction rates.

Alternatively, one can use t_{crown} , the crown group age:

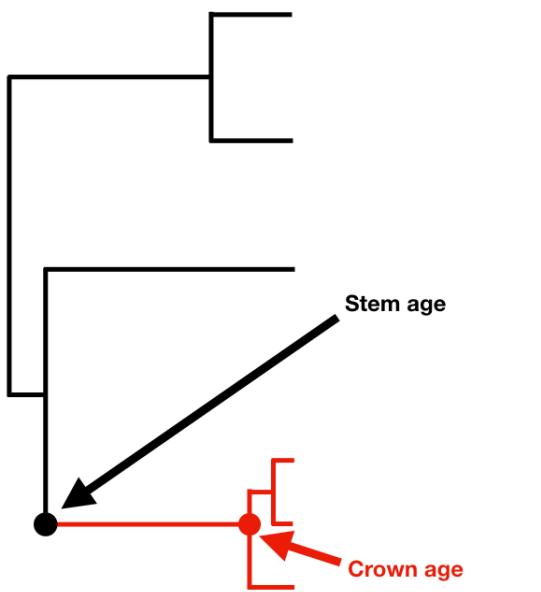

Figure 11.2. Crown and stem age of a clade of interest (highlighted in red).

(eq. 11.2)

$$\hat{r} = \frac{\ln(n) - \ln(2)}{t_{crown}}$$

The two equations differ because at the crown group age one is considering the clade's diversification starting with two lineages rather than one (Figure 11.2).

Even though these two equations reflect the balance of births and deaths through time, they give ML estimates for r only under a pure birth model where there is no extinction. If there has been extinction in the history of the clade, then our estimates using equations 11.1 and 11.2 will be biased. The bias comes from the fact that we see only clades that survive to the present day, and miss any clades of the same age that died out before they could be observed. By observing only the “winners” of the diversification lottery, we overestimate the net diversification rate. If we know the relative amount of extinction, then we can correct for this bias.

Under a scenario with extinction, one can define $\epsilon = \mu/\lambda$ and use the following method-of-moments estimators from Rohatgi (1976, following the notation of Magallon and Sanderson (2001)):

(eq. 11.3)

$$\hat{r} = \frac{\log[n(1 - \epsilon) + \epsilon]}{t_{stem}}$$

for stem age, and

(eq. 11.4)

$$\hat{r} = \frac{\ln\left[\frac{n(1-\epsilon^2)}{2} + 2\epsilon + \frac{(1-\epsilon)\sqrt{n(ne^2-8\epsilon+2ne+n)}}{2}\right] - \ln(2)}{t_{crown}}$$

for crown age. (Note that eq. 11.3 and 11.4 reduce to 11.1 and 11.2, respectively, when $\epsilon = 0$). Of course, we usually have little idea what ϵ should be. Common practice in the literature is to try a few different values for ϵ and see how the results change (e.g. Magallon and Sanderson 2001).

Magallón and Sanderson (2001), following Strathmann and Slatkin (1983), also describe how to use eq. 10.13 and 10.15 to calculate confidence intervals for the number of species at a given time.

As a worked example, let's consider the data in table 11.1, which give the crown ages and diversities of a number of plant lineages in the Páramo (from Madriñán et al. 2013). For each lineage, I have calculated the pure-birth estimate of speciation rate (from equation 11.2, since these are crown ages), and net diversification rates under three scenarios for extinction ($\epsilon = 0.1$, $\epsilon = 0.5$, and $\epsilon = 0.9$).

Lineage n	Age	\hat{r}_{pb}	$\hat{r}_{\epsilon=0.1}$	$\hat{r}_{\epsilon=0.5}$	$\hat{r}_{\epsilon=0.9}$
1	17	0.42	5.10	5.08	4.53
2	14	10.96	0.18	0.18	0.16
3	32	3.80	0.73	0.73	0.66
4	65	2.50	1.39	1.39	1.28
5	55	3.05	1.09	1.08	1.00
6	120	4.04	1.01	1.01	0.94
7	36	4.28	0.68	0.67	0.61
8	32	7.60	0.36	0.36	0.33
9	66	1.47	2.38	2.37	2.19
10	27	8.96	0.29	0.29	0.26
11	5	3.01	0.30	0.30	0.26
12	46	0.80	3.92	3.91	3.58
13	53	14.58	0.22	0.22	0.21

Table 11.1. Estimates of net diversification rates for Páramo lineages (data from Madriñán et al. 2013) using equations 11.2 and 11.4. Lineages are as follows: 1: Aragoa, 2: Arcytophyllum, 3: Berberis, 4: Calceolaria, 5: Draba, 6: Espeletiinae, 7: Festuca, 8: Jamesonia + Eriosorus, 9: Lupinus, 10: Lysipomia, 11: Oreobolus, 12: Puya, 13: Valeriana.

Inspecting the last four columns of Table 11.1, we can make a few general observations. First, these plant lineages really do have remarkably high diversification rates (Madriñán et al. 2013). Second, the net diversification rate we estimate depends on what we assume about relative extinction rates (ϵ). You can see in the table that the effect of extinc-

tion is relatively mild until extinction rates are assumed to be quite high ($\epsilon = 0.9$). Finally, assuming different levels of extinction affects the diversification rates but not their relative ordering. In all cases, net diversification rates for Aragoa, which formed 17 species in less than half a million years, is higher than the rest of the clades. This relationship holds only when we assume relative extinction rates are constant across clades, though. For example, the net diversification rate we calculate for Calceolaria with $\epsilon = 0$ is higher than the calculated rate for Aragoa with $\epsilon = 0.9$. In other words, we can't completely ignore the role of extinction in altering our view of present-day diversity patterns.

We can also estimate birth and death rates for clade ages and diversities using ML or Bayesian approaches. We already know the full probability distribution for birth-death models starting from any standing diversity $N(0) = n_0$ (see equations 10.13 and 10.15). We can use these equations to calculate the likelihood of any particular combination of N and t (either t_{stem} or t_{crown}) given particular values of λ and μ . We can then find parameter values that maximize that likelihood. Of course, with data from only a single clade, we cannot estimate parameters reliably; in fact, we are trying to estimate two parameters from a single data point, which is a futile endeavor. (It is common, in this case, to assume some level of extinction and calculate net diversification rates based on that, as we did in Table 11.1 above).

One can also assume that a set of clades have the same speciation and extinction rates and fit them simultaneously, estimating ML parameter values. This is the approach taken by Magallón and Sanderson (2001) in calculating diversification rates across angiosperms. When we apply this approach to the Paramo data, shown above, we obtain ML estimates of $\hat{r} = 0.27$ and $\hat{\epsilon} = 0$. If we were forced to estimate an overall average rate of speciation for all of these clades, this might be a reasonable estimate. However, the table above also suggests that some of these clades are diversifying faster than others. We will return to the issue of variation in diversification rates across clades in the next chapter.

We can also use a Bayesian approach to calculate posterior distributions for birth and death rates based on clade ages and diversities. This approach has not, to my knowledge, been implemented in any

software package, although the method is straightforward (for a related approach, see Höhna et al. 2016). To do this, we will modify the basic algorithm for Bayesian MCMC (see Chapter 2) as follows:

1. Sample a set of starting parameter values, r and ϵ , from their prior distributions. For this example, we can set our prior distribution for both parameters as exponential with a mean and variance of λ_{prior} (note that your choice for this parameter should depend on the units you are using, especially for r). We then select starting r and ϵ from their priors.
2. Given the current parameter values, select new proposed parameter values using the proposal density $Q(p'|p)$. For both parameter values, we can use a uniform proposal density with width w_p , so that $Q(p'|p) \sim U(p - w_p/2, p + w_p/2)$. We can either choose both parameter values simultaneously, or one at a time (the latter is typically more effective).
3. Calculate three ratios:
 - a. The prior odds ratio. This is the ratio of the probability of drawing the parameter values p and p' from the prior. Since we have exponential priors for both parameters, we can calculate this ratio as (eq. 11.5):

$$R_{prior} = \frac{\lambda_{prior} e^{-\lambda_{prior} p'}}{\lambda_{prior} e^{-\lambda_{prior} p}} = e^{\lambda_{prior} (p - p')}$$
 - b. The proposal density ratio. This is the ratio of probability of proposals going from p to p' and the reverse. We have already declared a symmetrical proposal density, so that $Q(p'|p) = Q(p|p')$ and $R_{proposal} = 1$.
 - c. The likelihood ratio. This is the ratio of probabilities of the data given the two different parameter values. We can calculate these probabilities from equations 10.13 or 10.16 (depending on if the data are stem ages or crown ages).
4. Find R_{accept} as the product of the prior odds, proposal density ratio, and the likelihood ratio. In this case, the proposal density ratio is 1, so (eq. 11.6):

$$R_{accept} = R_{prior} \cdot R_{likelihood}$$

5. Draw a random number u from a uniform distribution between 0 and 1. If $u < R_{accept}$, accept the proposed value of both parameters; otherwise reject, and retain the current value of the two parameters.
6. Repeat steps 2-5 a large number of times.

When we apply this technique to the Páromo (from Madriñán et al. 2013) and priors with $\lambda_{prior} = 1$ for both r and ϵ , we obtain posterior distributions: r (mean = 0.497, 95% CI = 0.08-1.77) and ϵ (mean = 0.36, 95% CI = 0.02-0.84; Figure 11.3). Note that these results are substantially different than the ML estimates. This is because in our Bayesian analysis our prior on extinction rates is exponential, giving a high probability for relatively strong levels of extinction relative to speciation.

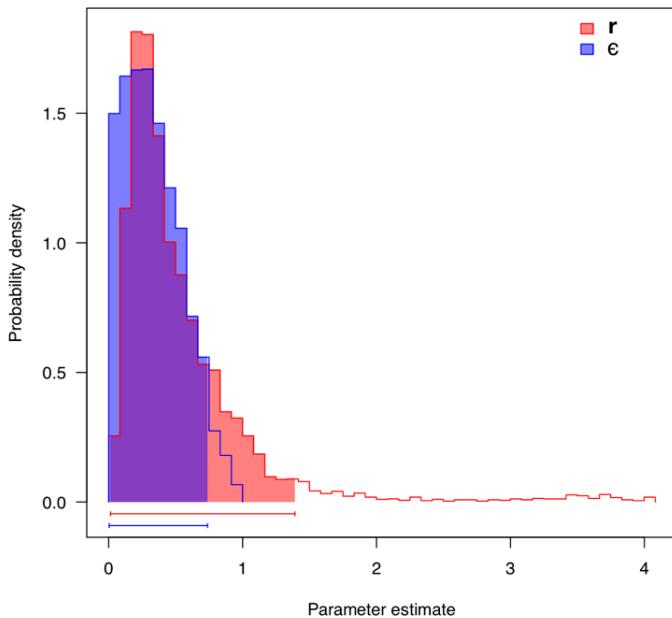

Figure 11.3. Posterior distribution for r and ϵ for Páromo clades (Madriñán et al. 2013).

Thus, we can estimate diversification rates from data on clade ages

and diversities. If we have a whole set of such clades, we can (in principal) estimate both speciation and extinction rates, so long as we are willing to assume that all of the clades share equal diversification rates. However, as we will see in the next section, this assumption is almost always dubious!

Section 11.3: Tree Balance

As we discussed in Chapter 10, tree balance considers how “balanced” the branches of a phylogenetic tree are. That is, if we look at each node in the tree, are the two sister clades of the same size (balanced) or wildly different (imbalanced)?

Birth-death trees have a certain amount of “balance,” perhaps a bit less than your intuition might suggest (see chapter 10). We can look to real trees to see if the amount of balance matches what we expect under birth-death models. A less balanced pattern in real trees would suggest that speciation and/or extinction rate vary among lineages more than we would expect. By contrast, more balanced trees would suggest more even and predictable diversification across the tree of life than expected under birth-death models. This approach traces back to Raup and colleagues, who applied stochastic birth-death models to paleontology in a series of influential papers in the 1970s (e.g. Raup et al. 1973, Raup and Gould (1974)). I will show how to do this for both individual nodes and for whole trees in the following sections.

Section 11.3a: Sister clades and the balance of individual nodes

For single nodes, we already know that the distribution of sister taxa species richness is uniform over all possible divisions of N_n species into two clades of size N_a and N_b (Chapter 11). This idea leads to simple test of whether the distribution of species between two sister clades is unusual compared to the expectation under a birth-death model (Slowinski and Guyer 1993). This test can be used, for example, to test whether the diversity of exceptional clades, like passerine birds,

is higher than one would expect when compared to their sister clade. This is the simplest measure of tree balance, as it only considers one node in the tree at a time.

Slowinsky and Guyer (1993) developed a test based on calculating a P-value for a division at least as extreme as seen in a particular comparisons of sister clades. We consider N_n total species divided into two sister clades of sizes N_a and N_b , where $N_a < N_b$ and $N_a + N_b = N_n$. Then:

(eq. 11.7) If $N_a \neq N_b$:

$$P = \frac{2N_a}{N_n - 1}$$

If $N_a = N_b$ or $P > 1$ then set $P = 1$

For example, we can assess diversification in the Andean representatives of the legume genus *Lupinus* (Hughes and Eastwood 2006). This genus includes one young radiation of 81 Andean species, spanning a wide range of growth forms. The likely sister clade to this spectacular Andean radiation is a clade of *Lupinus* species in Mexico that includes 46 species (Drummond et al. 2012). In this case $N_a = 81 - 46 = 35$, and we can then calculate a P-value testing the null hypothesis that both of these clades have the same diversification rate:

(eq. 11.8)

$$P = \frac{2N_a}{N_n - 1} = \frac{2 \cdot 35}{81 - 1} = 0.875$$

We cannot reject the null hypothesis. Indeed, later work suggests that the actual increase in diversification rate for *Lupinus* occurred deeper in the phylogenetic tree, in the ancestor of a more broadly ranging New World clade (Hughes and Eastwood 2006; Drummond et al. 2012).

Often, we are interested in testing whether a particular trait - say, dispersal into the Páramo - is responsible for the increase in species richness that we see in some clades. In that case, a single comparison of sister clades may be unsatisfying, as sister clades almost always differ in many characters, beyond just the trait of interest. Even if the clade with our putative “key innovation” is more diverse, we still might not

be confidence in inferring a correlation from a single observation. We need replication.

To address this problem, many studies have used natural replicates across the tree of life, comparing the species richnesses of many pairs of sister clades that differ in a given trait of interest. Following Slowinsky and Guyer (1993), we could calculate a p-value for each clade, and then combine those p-values into an overall test. In this case, one clade (with diversity N_1) has the trait of interest and the other does not (N_0), and our formula is half of equation 11.5 since we will consider this a one-tailed test:

(eq. 11.9)

$$P = \frac{N_0}{N_n - 1}$$

When analyzing replicate clade comparisons - e.g. many sister clades, where in each case one has the trait of interest and the other does not - Slowinsky and Guyer (1993) recommended combining these p-values using Fisher's combined probability test, so that:

(eq. 11.10)

$$\chi^2_{combined} = -2 \sum ln(P_i)$$

Here, the P_i values are from i independent sister clade comparisons, each using equation 11.9. Under the null hypothesis where the character of interest does not increase diversification rates, the test statistic, $\chi^2_{combined}$, should follow a chi-squared distribution with $2k$ degrees of freedom where k is the number of tests. But before you use this combined probability approach, see what happens when we apply it to a real example!

As an example, consider the following data, which compares the diversity of many sister pairs of plants. In each case, one clade has fleshy fruits and the other dry (data from Vamosi and Vamosi 2005):

Fleshy fruit clade	n_{fleshy}	Dry fruit clade	n_{dry}
A	1	B	2
C	1	D	64
E	1	F	300

Fleshy fruit clade	n_{fleshy}	Dry fruit clade	n_{dry}
G	1	H	89
I	1	J	67
K	3	L	4
M	3	N	34
O	5	P	10
Q	9	R	150
S	16	T	35
U	33	V	2
W	40	X	60
Y	50	Z	81
AA	100	BB	1
CC	216	DD	3
EE	393	FF	1
GG	850	HH	11
II	947	JJ	1
KK	1700	LL	18

The clades in the above table are as follows: A: *Pangium*, B: *Acharia*+*Kigellaria*, C: *Cyrilla*, D: *Clethra*, E: *Roussea*, F: *Lobelia*, G: *Myriophyllum* + *Haloragis* + *Penthorum*, H: *Tetracarpaea*, I: *Austrobaileya*, J: *Illicium*+*Schisandra*, K: *Davidsonia*, L: *Bauera*, M: *Mitchella*, N: *Pentas*, O: *Milligania* , P: *Borya*, Q: *Sambucus*, R: *Viburnum*, S: *Pereskia*, T: *Mollugo*, U: *Decaisnea* + *Sargentodoxa* + *Tinospora* + *Menispermum* + *Nandina* *Caulophyllum* + *Hydrastis* + *Glaucidium*, V: *Euptelea*, W: *Tetracera*, X: *Dillenia*, Y: *Osbeckia*, Z: *Mouriri*, AA: *Hippocratea*, BB: *Plagiopteron*, CC: *Cyclanthus* + *Sphaeradenia* + *Freycinetia*, DD: *Petrosavia* + *Japonlirion*, EE: *Bixa*, FF: *Theobroma* + *Grewia* + *Tilia* + *Sterculia* + *Durio*, GG: *Impatiens*, HH: *Idria*, II: *Lamium* + *Clerodendrum* + *Callicarpa* + *Phyla* + *Pedicularis* + *Paulownia*, JJ: *Euthystachys*, KK: *Callicarpa* + *Phyla* + *Pedicularis* + *Paulownia* + *Solanum*, LL: *Solanum*.

The individual clades show mixed support for the hypothesis, with only 7 of the 18 comparisons showing higher diversity in the fleshy clade, but 6 of those 7 comparisons significant at $P < 0.05$ using equation 11.9. The combined probability test gives a test statistic of $\chi^2_{combined} = 72.8$.

Comparing this to a χ^2 distribution with 36 degrees of freedom, we obtain $P = 0.00027$, a highly significant result. This implies that fleshy fruits do, in fact, result in a higher diversification rate.

However, if we test the opposite hypothesis, we see a problem with the combined probability test of equation 11.10 (Vamosi and Vamosi 2005). First, notice that 11 of 18 comparisons show higher diversity in the non-fleshy clade, with 4 significant at $P < 0.05$. The combined probability test gives $\chi^2_{combined} = 58.9$ and $P = 0.0094$. So we reject the null hypothesis and conclude that non-fleshy fruits diversify at a higher rate! In other words, we can reject the null hypothesis in both directions with this example.

What's going on here? It turns out that this test is very sensitive to outliers - that is, clades with extreme differences in diversity. These clades are very different than what one would expect under the null hypothesis, leading to rejection of the null - and, in some cases with two characters, when there are outliers on both sides (e.g. the proportion of species in each state has a u-shaped distribution; Paradis 2012) we can show that both characters significantly increase diversity (Vamosi and Vamosi 2005)!

Fortunately, there are a number of improved methods that can be used that are similar in spirit to the original Slowinsky and Guyer test but more statistically robust (e.g Paradis 2012). For example, we can apply the “richness Yule test” as described in Paradis (2012), to the data from Vamosi et al. (2005). This is a modified version of the McConway-Sims test (McConway and Sims 2004), and compares the likelihood of a equal rate yule model applied to all clades to a model where one trait is associated with higher or lower diversification rates. This test requires knowledge of clade ages, which I don't have for these data, but Paradis (2012) shows that the test is robust to this assumption and recommends substituting a large and equal age for each clade. I chose 1000 as an arbitrary age, and found a significant likelihood ratio test (null model $lnL = -215.6$, alternative model $lnL = -205.7$, $P = 0.000008$). This method estimates a higher rate of diversification for fleshy fruits (since the age of the clade is arbitrary, the actual rates are not meaningful, but their estimated ratio $\lambda_1/\lambda_0 = 1.39$ suggests that fleshy fruited lineages have a diversification rate almost 40% higher).

Section 11.3b: Balance of whole phylogenetic tremendous

We can assess the overall balance of an entire phylogenetic tree using tree balance statistics. As discussed, I will describe just one common statistic, Colless' I , since other metrics capture the same pattern in slightly different ways.

To calculate Colless' I , we can use equation 10.18. This result will depend strongly on tree size, and so is not comparable across trees of different sizes; to allow comparisons, I_c is usually standardized by subtracting the expected mean for trees of that size under an ERM model, and dividing by the standard deviation. Both of these can be calculated analytically (Blum et al. 2006), and standardized I_c calculated using a small approximation (following Bortolussi et al. 2006) as:

(eq. 11.11)

$$I'_c = \frac{I_c - n * \log(n) - n(\gamma - 1 - \log(2))}{n}$$

Since the test statistics are based on descriptions of patterns in trees rather than particular processes, the relationship between imbalance and evolutionary processes can be difficult to untangle! But all tree balance indices allow one to reject the null hypothesis that the tree was generated under a birth-death model. Actually, the expected patterns of tree balance are absolutely identical under a broader class of models called “Equal-Rates Markov” (ERM) models (Harding 1971; Mooers and Heard 1997). ERM models specify that diversification rates (both speciation and extinction) are equal across all lineages for any particular point in time. However, those rates may or may not change through time. If they don't change through time, then we have a constant rate birth-death model, as described above - so birth-death models are ERM models. But ERM models also include, for example, models where birth rates slow through time, or extinction rates increase through time, and so on. As long as the changes in rates occur in exactly the same way across all lineages at any time, then all of these models predict exactly the same pattern of tree balance.

Typical steps for using tree balance indices to test the null hypothesis that the tree was generated under an ERM model are as follows:

1. Calculate tree balance using a tree balance statistic.
2. Simulate pure birth trees to generate a null distribution of the test statistic. We are considering the set of ERM models as our null, but since pure-birth is simple and still ERM we can use it to get the correct null distribution.
3. Compare the actual test statistic to the null distribution. If the actual test statistic is in the tails of the null distribution, then your data deviates from an ERM model.

Step 2 is unnecessary in cases where we know null distributions for tree balance statistics analytically, true for some (but not all) balance metrics (e.g. Blum and François 2006). There are also some examples in the literature of considering null distributions other than ERM. For example, Mooers and Heard (1997) consider two other null models, PDA and EPT, which consider different statistical distributions of tree shapes (but both of these are difficult to tie to any particular evolutionary process).

Typically, phylogenetic trees are more imbalanced than expected under the ERM model. In fact, this is one of the most robust generalizations that one can make about macroevolutionary patterns in phylogenetic trees. This deviation means that diversification rates vary among lineages in the tree of life. We will discuss how to quantify and describe this variation in later chapters. These tests are all similar in that they use multiple non-nested comparisons of species richness in sister clades to calculate a test statistic, which is then compared to a null distribution, usually based on a constant-rates birth-death process (reviewed in Vamosi and Vamosi 2005; Paradis 2012).

As an example, we can apply the whole-tree balance approach to the tree of *Lupinus* (Drummond et al. 2012). For this tree, which has 137 tips, we calculate $I_c = 1010$ and $I'_c = 3.57$. This is much higher than expected by chance under an ERM model, with $P = 0.0004$. That is, our tree is significantly more imbalanced than expected under a ERM model, which includes both pure birth and birth-death. We can safely conclude that there is variation in speciation and/or extinction rates across lineages in the tree.

Section 11.4: Fitting birth-death models to branching times

Another approach that uses more of the information in a phylogenetic tree involves fitting birth-death models to the distribution of branching times. This approach traces all the way back to Yule (1925), who first applied stochastic process models to the growth of phylogenetic trees. More recently, a series of papers by Raup and colleagues (Raup et al. 1973; Raup and Gould 1974; Gould et al. 1977; Raup 1985) spurred modern approaches to quantitative macroevolution by simulating random clades, then demonstrating how variable such clades grown under simple birth-death models can be.

Most modern approaches to fitting birth-death models to phylogenetic trees use the intervals between speciation events on a tree - the “waiting times” between successive speciation - to estimate the parameters of birth-death models. Figure 10.2 shows these waiting times. Frequently, information about the pattern of species accumulation in a phylogenetic tree is summarized by a lineage-through-time (LTT) plot, which is a plot of the number of lineages in a tree against time (see Figure 10.9). As I introduced in Chapter 10, the y-axis of LTT plots is log-transformed, so that the expected pattern under a constant-rate pure-birth model is a straight line. Note also that LTT plots ignore the relative order of speciation events. Stadler (2013b) calls models justifying such an approach “species-exchangable” models - we can change the identity of species at any time point without changing the expected behavior of the model. Because of this, approaches to understanding birth-death models based on branching times are different from - and complementary to - approaches based on tree topology, like tree balance.

As discussed in the previous chapter, even though we often have no information about extinct species in a clade, we can still (in theory) infer the presence of extinction from an LTT plot. The signal of extinction is an excess of young lineages, which is seen as the “pull of the recent” in our LTT plots (Figure 10.10). In the next chapter, I will demonstrate how statistical approaches can capture this pattern in a more rigorous way.

Section 11.4a: Likelihood of waiting times under a birth-death model

In order to use ML and Bayesian methods for estimating the parameters of birth-death models from comparative data, we need to write down the likelihoods of the waiting times between speciation events in a tree. There is a little bit of variation in notation in the literature, so I will follow Stadler (2013b) and Maddison et al. (2007), among others, to maintain consistency. We will assume that the clade begins at time t_1 with a pair of species. Most analyses follow this convention, and condition the process as starting at the time t_1 , representing the node at the root of the tree. This makes sense because we rarely have information on the stem age of our clade. We will also condition on both of these initial lineages surviving to the present day, as this is a requirement to obtain a tree with this crown age (e.g. Stadler 2013a equation 5).

Speciation and extinction events occur at various times, and the process ends at time 0 when the clade has n extant species - that is, we measure time backwards from the present day. Extinction will result in species that do not extend all the way to time 0. For now, we will assume that we only have data on extant species. We will refer to the phylogenetic tree that shows branching times leading to the extant species as the reconstructed tree (Nee et al. 1994). For a reconstructed tree with n species, there are $n - 1$ speciation times, which we will denote as $t_1, t_2, t_3, \dots, t_{n-1}$. The leaves of our ultrametric tree all terminate at time 0.

Note that in this notation, $t_1 > t_2 > \dots > t_{n-1} > 0$, that is, our speciation times are measured backwards from the tips, and as we increase the index the times are constantly decreasing [this is an important notational difference between Stadler (2013a), used here, and Nee (1994 and others), the latter of which considers the time intervals between speciation events, e.g. $t_1 - t_2$ in our notation]. For now, we will assume complete sampling; that is, all n species alive at the present day are represented in the tree.

We will now derive a likelihood of observing the set of speciation times t_1, t_2, \dots, t_{n-1} given the extant diversity of the clade, n , and our birth-death model parameters λ and μ . To do this, we will follow

very closely an approach based on differential equations introduced by Maddison et al. (2007).

The general idea is that we will assign values to these probabilities at the tips of the tree, and then define a set of rules to update them as we flow back through the tree from the tips to the root. When we arrive at the root of the tree, we will have the probability of observing the actual tree given our model - that is, the likelihood. This is another pruning algorithm.

To begin with, we need to keep track of two probabilities: $D_N(t)$, the probability that a lineage at some time t in the past will evolve into the extant clade N as observed today; and $E(t)$, the probability that a lineage at some time t will go completely extinct and leave no descendants at the present day. (Later, we will redefine $E(t)$ so that it includes the possibility that the lineages has descendants but none have been sampled in our data). We then apply these probabilities to the tree using three main ideas (Figure 11.4)

1. We define our starting points at the tips of the tree.
2. We define how the probabilities defined in (1) change as we move backwards along branches of the tree.
3. We define what happens to our probabilities at the tree nodes.

Then, starting at the tips of the tree, we make our way to the root. At each tip, we have a starting value for both $D_N(t)$ and $E(t)$. We move backwards along the branches of the tree, updating both probabilities as we go using step 2. When two branches come together at a node, we combine those probabilities using step 3.

In this way, we walk through the tree, starting with the tips and passing over every branch and node (Figure 11.4). When we get to the root we will have $D_N(t_{root})$, which is the full likelihood that we want.

You might wonder why we need to calculate both $D_N(t)$ and $E(t)$ if the likelihood is captured by $D_N(t)$ at the root. The reason is that the probability of observing a tree is dependent on these extinction probabilities calculated back through time. We need to keep track of $E(t)$ to know about $D_N(t)$ and how it changes. You will see below that $E(t)$ appears directly in our differential equations for $D_N(t)$.

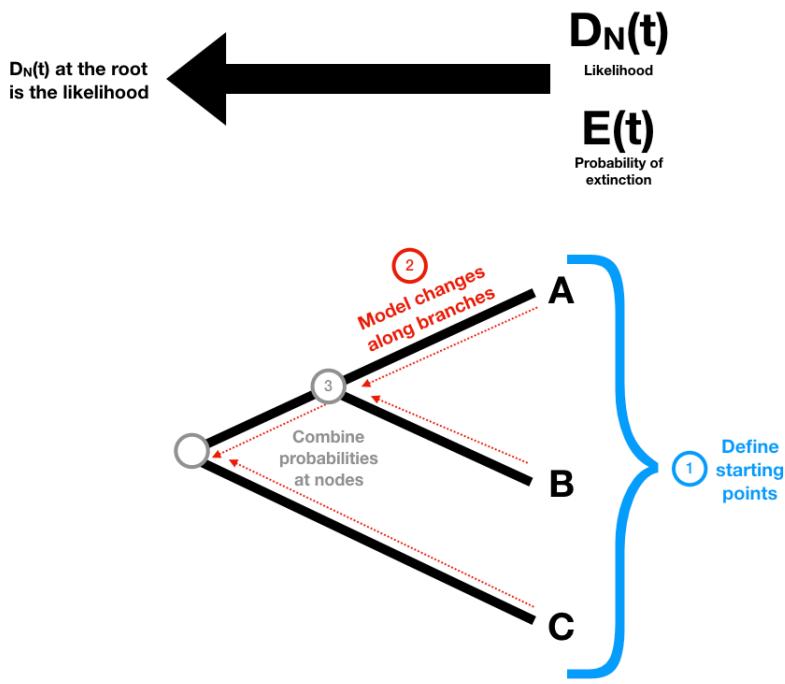

Figure 11.4. General outline of steps for calculating likelihood of a tree under a birth-death model (Maddison et al. 2007)

First, the starting point. Since every tip i represents a living lineage, we know it is alive at the present day - so we can define $D_N(t) = 1$. We also know that it will not go extinct before being included in the tree, so $E(t) = 0$. This gives our starting values for the two probabilities at each tip in the tree (Figure 11.5).

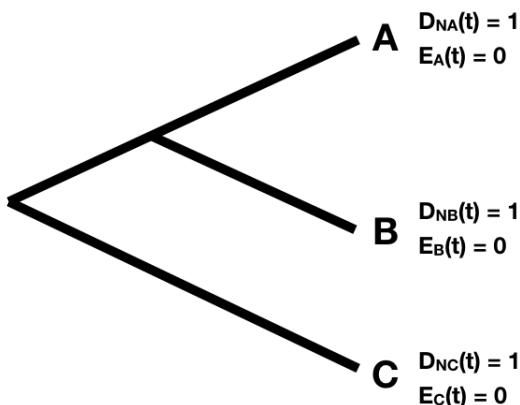

Figure 11.5. Starting points at tree tips for likelihood probability calculations (Maddison et al. 2007).

Next, imagine we move backwards along some section of a tree branch with no nodes. We will consider an arbitrary branch of the tree. Since we are going back in time, we will start at some node in the tree N , which occurs at a time t_N , and denote the time going back into the past as t (Figure 11.6).

Since that section of branch exists in our tree, we know two things: the lineage did not go extinct during that time, and if speciation occurred, the lineage that split off did not survive to the present day. We can capture these two possibilities in a differential equation that considers

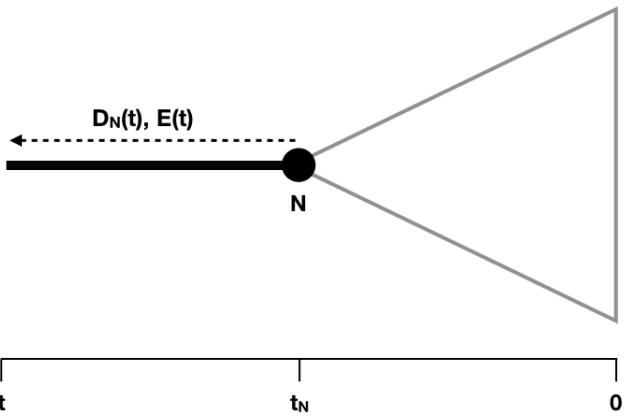

Figure 11.6. Updating $D_N(t)$ and calculating $E(t)$ along a tree branch (Maddison et al. 2007).

how our overall likelihood changes over some very small unit of time (Maddison et al. 2007).

(eq. 11.12)

$$\frac{dD_N(t)}{dt} = -(\lambda + \mu)D_N(t) + 2\lambda E(t)D_N(t)$$

Here, the first part of the equation, $-(\lambda + \mu)D_N(t)$, represents the probability of not speciating nor going extinct, while the second part, $2\lambda E(t)D_N(t)$, represents the probability of speciation followed by the ultimate extinction of one of the two daughter lineages. The 2 in this equation appears because we must account for the fact that, following speciation from an ancestor to daughters A and B, we would see the same pattern no matter which of the two descendants survived to the present.

We also need to calculate our extinction probability going back through the tree (Maddison et al. 2007):

(eq. 11.13)

$$\frac{dE(t)}{dt} = \mu - (\mu + \lambda)E(t) + \lambda E(t)^2$$

The three parts of this equation represent the three ways a lineage might not make it to the present day: either it goes extinct during the interval being considered (μ), it survives that interval but goes extinct some time later $-(\mu + \lambda)E(t)$, or it speciates in the interval but both descendants go extinct before the present day ($\lambda E(t)^2$) (Maddison et al. 2007). Unlike the $D_N(t)$ term, this probability depends only on time and not the topological structure of the tree.

We will also specify that $\lambda > \mu$; it is possible to relax that assumption, but it makes the solution more complicated.

We can solve these equations so that we will be able to update the probability moving backwards along any branch of the tree with length t . First, solving equation 11.13 and using our initial condition $E(0) = 0$:

(eq. 11.14)

$$E(t) = 1 - \frac{\lambda - \mu}{\lambda - (\lambda - \mu)e^{(\lambda - \mu)t}}$$

We can now substitute this expression for $E(t)$ into eq. 11.12 and solve.
 (eq. 11.15)

$$D_N(t) = e^{-(\lambda-\mu)(t-t_N)} \frac{(\lambda - (\lambda - \mu)e^{(\lambda-\mu)t_N})^2}{(\lambda - (\lambda - \mu)e^{(\lambda-\mu)t})^2} \cdot D_N(t_N)$$

Remember that t_N is the depth (measured from the present day) of node N (Figure 11.6).

Finally, we need to consider what happens when two branches come together at a node. Since there is a node, we know there has been a speciation event. We multiply the probability calculations flowing down each branch by the probability of a speciation event [Maddison et al. (2007); Figure 11.7].

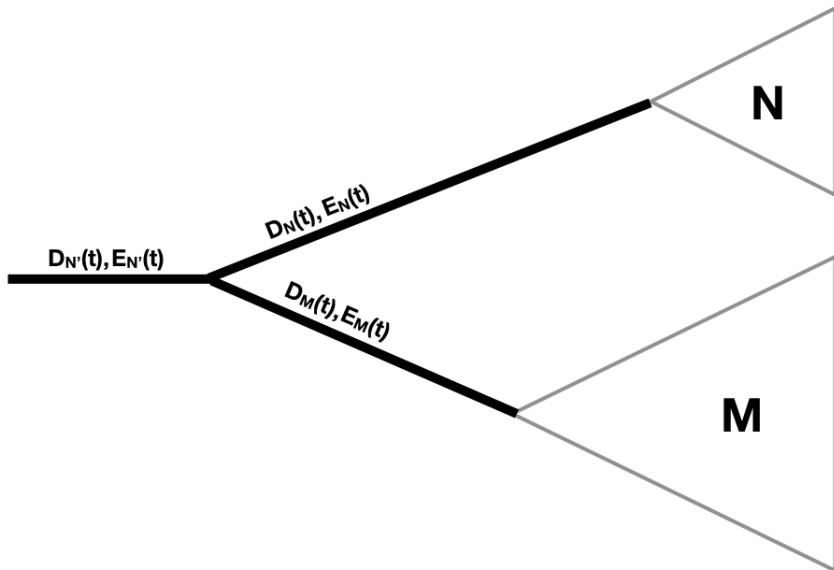

Figure 11.7. Updating $D_N(t)$ and $E(t)$ along a tree branch (Maddison et al. 2007).

So:

(eq. 11.16)

$$D_{N'}(t) = D_N(t)D_M(t)\lambda$$

Where clade N' is the clade made up of the combination of two sister clades N and M.

To apply this approach across an entire phylogenetic tree, we multiply equations 11.15 and 11.16 across all branches and nodes in the tree. Thus, the full likelihood is (Maddison et al. 2007; Morlon et al. 2011):

(eq. 11.17)

$$L(t_1, t_2, \dots, t_n) = \lambda^{n-1} \left[\prod_{k=1}^{2n-2} e^{(\lambda-\mu)(t_{k,b}-t_{k,t})} \cdot \frac{(\lambda - (\lambda - \mu)e^{(\lambda-\mu)t_{k,t}})^2}{(\lambda - (\lambda - \mu)e^{(\lambda-\mu)t_{k,b}})^2} \right]$$

Here, n is the number of tips in the tree (note that the original derivation in Maddison uses n as the number of nodes, but I have changed it for consistency with the rest of the book).

The product in equation 11.17 is taken over all $2n - 2$ branches in the tree. Each branch k has two times associated with it, one towards the base of the tree, $t_{k,b}$, and one towards the tips, $t_{k,t}$.

Most methods fitting birth-death models to trees condition on the existence of a tree - that is, conditioning on the fact that the whole process did not go extinct before the present day, and the speciation event from the root node led to two surviving lineages. To do this conditioning, we divide equation 11.17 by $\lambda[1 - E(t_{root})]^2$ (Morlon et al. 2011; Stadler 2013a).

Additionally, likelihoods for birth-death waiting times, for example those in the original derivation by Nee, include an additional term, $(n - 1)!$. This is because there are $(n - 1)!$ possible topologies for any set of $n - 1$ waiting times, all equally likely. Since this term is constant for a given tree size n , then leaving it out has no influence on the relative likelihoods of different parameter values - but it is necessary to know about this multiplier if comparing likelihoods across different models for model selection, or comparing the output of different programs (Stadler 2013a).

Accounting for these two factors, the full likelihood is:

(eq. 11.18)

$$L(\tau) = (n - 1)! \frac{\lambda^{n-2} \left[\prod_{k=1}^{2n-2} e^{(\lambda-\mu)(t_{k,b}-t_{k,t})} \cdot \frac{(\lambda-(\lambda-\mu)e^{(\lambda-\mu)t_{k,t}})^2}{(\lambda-(\lambda-\mu)e^{(\lambda-\mu)t_{k,b}})^2} \right]}{[1 - E(t_{root})]^2}$$

where:

(eq. 11.19)

$$E(t_{root}) = 1 - \frac{\lambda - \mu}{\lambda - (\lambda - \mu)e^{(\lambda - \mu)t_{root}}}$$

Section 11.4b: Using maximum likelihood to fit a birth-death model

Given equation 11.19 for the likelihood, we can estimate birth and death rates using both ML and Bayesian approaches. For the ML estimate, we maximize equation 11.19 over λ and μ . For a pure-birth model, we can set $\mu = 0$, and the maximum likelihood estimate of λ can be calculated analytically as:

(eq. 11.20)

$$\lambda = \frac{n - 2}{s_{branch}}$$

where s_{branch} is the sum of branch lengths in the tree,

(eq. 11.21)

$$s_{branch} = \sum_{i=1}^{n-1} t_i + t_{n-1}$$

Equation 11.21 is also called the Kendal-Moran estimator of the speciation rate (Nee 2006).

For a birth-death model, we can use numerical methods to maximize the likelihood over λ and μ .

For example, we can use ML to fit a birth-death model to the *Lupinus* tree (Drummond et al. 2012), which has 137 tip species and a total age of 16.6 million years. Doing so, we obtain ML parameter estimates

of $\lambda = 0.46$ and $\mu = 0.20$, with a log-likelihood of $\ln L_{bd} = 262.3$. Compare this to a pure birth model on the same tree, which gives $\lambda = 0.35$ and $\ln L_{pb} = 260.4$. One can compare the fit of these two models using AIC scores: $AIC_{bd} = -520.6$ and $AIC_{pb} = -518.8$, so the birth-death model has a better (lower) AIC score but by less than two AIC units. A likelihood ratio test, which gives $\Delta = 3.7$ and $P = 0.054$. In other words, we estimate a non-zero extinction rate in the clade, but the evidence supporting that model over a pure-birth model is not particularly strong. Even if this model selection is a bit ambiguous, remember that we have also estimated parameters using all of the information that we have in the waiting times of the phylogenetic tree.

Section 11.4c: Using Bayesian MCMC to fit a birth-death model

We can also estimate birth and death rates using a Bayesian MCMC. We can use exactly the method spelled out above for clade ages and diversities, but substitute equation 11.11 for the likelihood, thus using the waiting times derived from a phylogenetic tree to estimate model parameters.

Applying this to Lupines with the same priors as before, we obtain the posterior distributions shown in figure 11.5. The mean of the posterior for each parameter is $\lambda = 0.48$ and $\mu = 0.23$, quite close to the ML estimates for these parameters.

Section 11.5: Sampling and birth-death models

It is important to think about sampling when fitting birth-death models to phylogenetic trees. If any species are missing from your phylogenetic tree, they will lead to biased parameter estimates. This is because missing species are disproportionately likely to connect to the tree on short, rather than long, branches. If we randomly sample lineages from a tree, we will end up badly underestimating both speciation and extinction rates (and wrongly inferring slowdowns; see chapter 12).

Fortunately, the mathematics for incomplete sampling of reconstructed

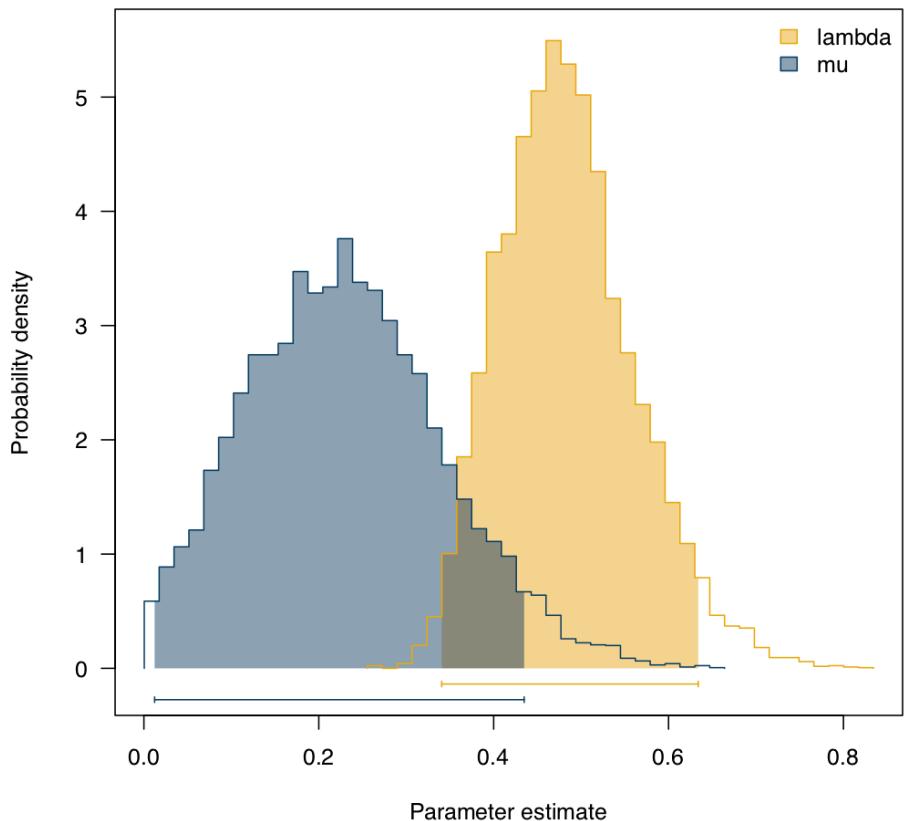

Figure 11.8. Posterior distribution for b and d for *Lupinus* (Drummond et al. 2012).

phylogenetic trees has also been worked out. There are two ways to do this, depending on how the tree is actually sampled. If we consider the missing species to be random with respect to the taxa included in the tree, then one can use a uniform sampling fraction to account for them. By contrast, we often are in the situation where we have tips in our tree that are single representatives of diverse clades (e.g. genera). We usually know the diversity of these unsampled clades in our tree of representatives. I will follow (Höhna et al. 2011; Höhna 2014) and refer to this approach as *representative sampling* (and the previous alternative as *uniform sampling*).

For the uniform sampling approach, we use the framework above of calculating backwards through time, but modify the starting points for each tip in the tree to reflect f , the probability of sampling a species (following Fitzjohn et al. (2009)):

(eq. 11.22)

$$D_N(0) = 1 - f$$

$$E(0) = f$$

Repeating the calculations above along branches and at nodes, but with the starting conditions above, we obtain the following likelihood (FitzJohn et al. 2009):

(eq. 11.23)

$$L(t_1, t_2, \dots, t_n) = \lambda^{n-1} \left[\prod_{k=1}^{2n-2} e^{(\lambda-\mu)(t_{k,b}-t_{k,t})} \cdot \frac{(f\lambda - (\mu - \lambda(1-f))e^{(\lambda-\mu)t_{k,t}})^2}{(f\lambda - (\mu - \lambda(1-f))e^{(\lambda-\mu)t_{k,b}})^2} \right]$$

Again, the above formula is proportional to the full likelihood, which is:

(eq. 11.24)

$$L(\tau) = (n-1)! \frac{\lambda^{n-2} \left[\prod_{k=1}^{2n-2} e^{(\lambda-\mu)(t_{k,b}-t_{k,t})} \cdot \frac{(f\lambda - (\mu - \lambda(1-f))e^{(\lambda-\mu)t_{k,t}})^2}{(f\lambda - (\mu - \lambda(1-f))e^{(\lambda-\mu)t_{k,b}})^2} \right]}{[1 - E(t_{root})]^2}$$

and:

(eq. 11.25)

$$E(t_{root}) = 1 - \frac{\lambda - \mu}{\lambda - (\lambda - \mu)e^{(\lambda - \mu)t_{root}}}$$

For representative sampling, one approach is to consider the data as divided into two parts, phylogenetic and taxonomic. The taxonomic part is the stem age and extant diversity of the unsampled clades, while the phylogenetic part is the relationships among those clades. Following Rabosky and Lovette (2007), we can then calculate:

(eq. 11.26)

$$L_{total} = L_{phylogenetic} \cdot L_{taxonomic}$$

Where $L_{phylogenetic}$ can be calculated using equation 11.18 and $L_{taxonomic}$ calculated for each clade using equation 10.16 and then multiplied to get the overall likelihood.

There are two extensions to this approach that are worth mentioning. One is Hohna's (2011) diversified sampling ("DS") model. This model makes a different assumption: when sampling n taxa from an overall set of m , the deepest $n-1$ nodes have been included. Hohna's approach allows users to fit a model with representative sampling but without requiring assignment of extant diversity to each clade. Another approach, by Stadler and Smrckova (2016), calculates likelihoods for representatively sampled trees and can fit models of time-varying speciation and extinction rates (see chapter 12).

Section 11.6: Summary

In this chapter, I described how to estimate parameters from birth-death models using data on species diversity and ages, and how to use patterns of tree balance to test hypotheses about changing birth and death rates. I also described how to calculate the likelihood for birth-death models on trees, which leads directly to both ML and Bayesian methods for estimating birth and death rates. In the next chapter,

we will explore elaborations on birth-death models, and discuss models that go beyond constant-rates birth-death models to analyze the diversity of life on Earth.

Chapter 12: Beyond birth-death models

Section 12.1: Capturing variable evolution

As we discovered in Chapter 11], there are times and places where the tree of life has grown more rapidly than others. For example, islands and island-like habitats are sometimes described as hotspots of speciation (Losos and Schlüter 2000; Hughes and Eastwood 2006), and diversification rates in such habitats can proceed at an extremely rapid pace. On a broader scale, many studies have shown that speciation rates are elevated and/or extinction rates depressed following mass extinctions (e.g. Sepkoski 1984). Finally, some clades seem to diversify much more rapidly than others. In my corner of the world, the Pacific Northwest of the United States, this variation is best seen in our local amphibians. We have species like the spotted frog and the Pacific tree frog, which represent two very diverse frog lineages with high diversification rates (Ranidae and Hylidae, respectively; Roelants et al. 2007). At the same time, if one drives a bit to the high mountain streams, you can find frogs with tiny tails. These Inland Tailed Frogs are members of *Ascaphidae*, a genus with only two species, one coastal and one inland. (As an aside, the tail, found only in males, is an intromittent organ used for internal fertilization - analogous to a penis, but different!) These two tailed frog species are the sister group to a small radiation of four species frogs in New Zealand (*Leopelmatidae*, which have no tails). These two clades together - just six species - make up the sister clade to all other frogs, nearly 7000 species (Roelants et al. 2007; Jetz and Pyron 2018). We seek to explain patterns like this contrast in the diversity of two groups which descend from a common ancestor and are, thus, the same age.

Simple, constant-rate birth-death models are not adequate to capture the complexity and dynamics of speciation and extinction across the tree of life. Speciation and extinction rates vary through time, across clades, and among geographic regions. We can sometimes predict this variation based on what we know about the mechanisms that lead to speciation and/or extinction.

In this chapter, I will explore some extensions to birth-death models

Figure 12.1. Contrasts in frog diversity. Spotted frogs (A) and Pacific tree frogs (B) come from diverse clades, while tailed frogs (C) and New Zealand frogs (D) are from depauperate clades. Photo sources: all from Wikimedia Commons A - photo by Sean Neilsen; B - photo by The High Fin Sperm Whale C - photo by Raymond; D - photo by Phil Bishop.

that allow us to explore diversification in more detail. This chapter also leads naturally to the next, chapter 13, which will consider the case where diversification rates depend on species' traits.

Section 12.2: Variation in diversification rates across clades

We know from analyses of tree balance that the tree of life is more imbalanced than birth-death models predict. We can explore this variation in diversification rates by allowing birth and death models to vary along branches in phylogenetic trees. The simplest scenario is when one has a particular prediction about diversification rates to test. For example, we might wonder if diversification rates in one clade (clade A in Figure 12.2) is higher than in the rest of the phylogenetic tree. We can test this hypothesis by fitting a multiple-rate birth-death model.

The simplest method to carry out this test is by using model selection in a ML framework (Rabosky et al. 2007). To do this, we first fit a constant-rates birth-death model to the entire tree, and calculate a likelihood. We can then fit variable-rates birth-death models to the data, comparing the fit of these models using either likelihood ratio tests or AIC_C . The simplest way to fit a variable-rates model is to adapt the likelihood formula in equation 11.18 (or eq. 11.24 if species are unsampled). We calculate the likelihood in two parts, one for the background part of the tree (with rates λ_B and μ_B) and one for the focal clade that may have different diversification dynamics (with rates λ_A and μ_A). We can then compare this model to one where speciation and extinction rates are constant through time.

Consider the example in Figure 12.2. We would like to know whether clade A has speciation and extinction rates, λ_A and μ_A , that differ from the background rates, λ_B and μ_B – we will call this a “variable rates” model. The alternative is a “constant rates” model where the entire clade has constant rate parameters λ_T and μ_T . These two models are nested, since the constant-rates model is a special case of the variable rates model where $\lambda_T = \lambda_A = \lambda_B$ and $\mu_T = \mu_A = \mu_B$. Calculating the likelihood for these two models is reasonably straightforward - we simply calculate the likelihood for each section of the tree using the

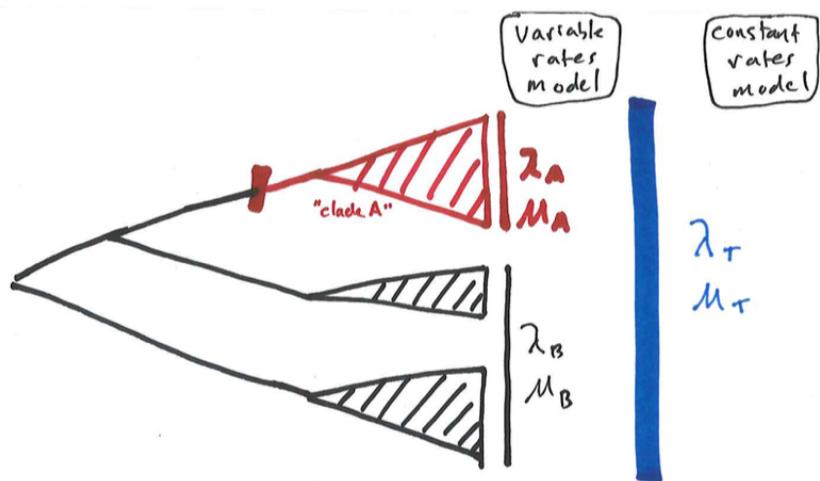

Figure 12.2. A phylogenetic tree including three clades, illustrating two possible models for diversification: a constant rates model, where all three clades have the same diversification parameters λ_T and μ_T , and a variable rates model, where clade A has parameters (λ_A and μ_A) that differ from those of the other two clades (λ_B and μ_B).

relevant equation from Chapter 11, and then multiply the likelihoods from the two parts of the tree (or add the log-likelihoods) to get the overall likelihood.

For a real example, let's look at the phylogenetic tree of amphibians and evaluate the hypothesis that the tailed and New Zealand frogs, sister clade to the rest of frogs, diversified at a slower rate than other amphibians (Figure 12.3). We can use the phylogenetic “backbone” tree from Jetz and Pyron (Jetz and Pyron 2018), assigning diversities based on the classification associated with that publication. We can then calculate likelihoods based on equation 11.24.

We can calculate the likelihood of the constant rates model, with two parameters λ_T and μ_T , to a variable rates model with four parameters λ_{liop} , μ_{liop} , λ_{other} , and μ_{other} . For this example, we obtain the following results.

Model	Parameter estimates	ln-Likelihood	AIC_c
Constant rates	$\lambda_T = 0.30$ $\mu_T = 0.28$	-1053.9	2111.8
Variable rates	$lambda_{liop} = 0.010$ $\mu_{liop} = 0.007$ $lambda_{other} = 0.29$ $\mu_{other} = 0.27$	-1045.4	2101.1

With a difference in AIC_c of more than 10, we see from these results that there is good reason to think that there is a difference in diversification rates in these “oddball” frogs compared to the rest of the amphibians.

Of course, more elaborate comparisons are possible. For example, one could compare the fit of four models, as follows: Model 1, constant rates; Model 2, speciation rate in clade A differs from the background; Model 3, extinction rate in clade A differs from the background; and Model 4, both speciation and extinction rates in clade A differ from the background. In this case, some of the pairs of models are nested – for example, Model 1 is a special case of Model 2, which is, in turn, a special case of Model 4 – but all four do not make a nested series.

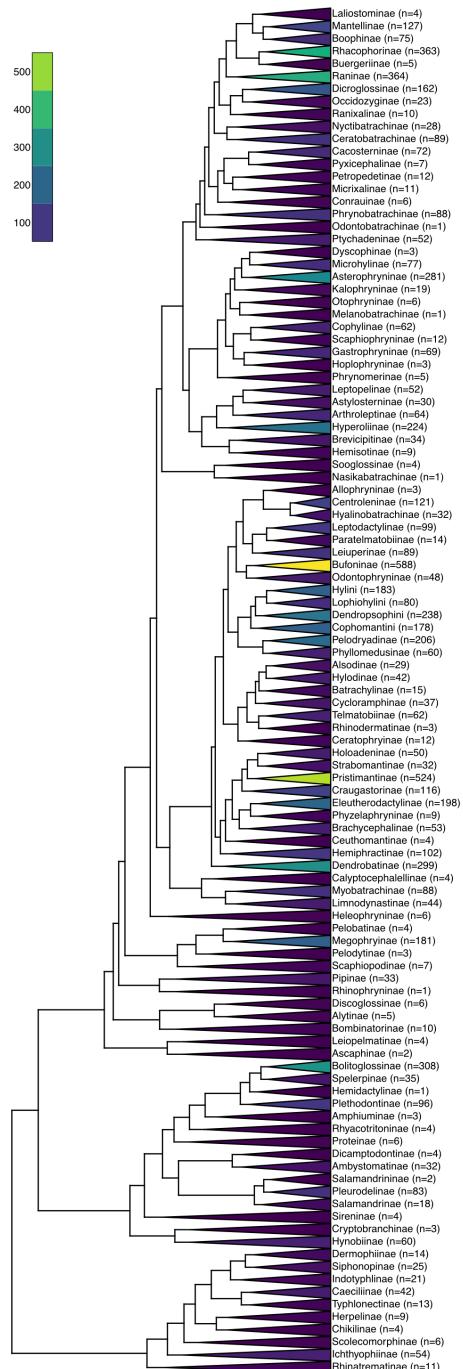

Figure 12.3. Phylogenetic tree of amphibians with divergence times and diversities of major clades.

Here we benefit from using a model selection approach based on AIC_C . We can fit all four models and use their relative number of parameters to calculate AIC_C scores. We can then calculate AIC_C weights to evaluate the relative support for each of these four models. (As an aside, it might be difficult to differentiate among these four possibilities without a lot of data!)

But what if you do not have an a priori reason to predict differential diversification rates across clades? Or, what if the only reason you think one clade might have a different diversification rate than another is that it has more species? (Such reasoning is circular, and will wreak havoc with your analyses!) In such cases, we can use methods that allow us to fit general models where diversification rates are allowed to vary across clades in the tree. Available methods use stepwise AIC (MEDUSA, Alfaro et al. 2009; but see May and Moore 2016), or reversible-jump Bayesian MCMC (Rabosky 2014, 2017; but see Moore et al. 2016).

For example, running a stepwise-AIC algorithm on the amphibian data (Alfaro et al. 2009) results in a model with 11 different speciation and extinction regimes (Figure 12.4). This is good evidence that diversification rates have varied wildly through the history of amphibians.

One note: all current approaches fit a model where birth and death rates change at discrete times in the phylogenetic tree - that is, along certain branches in the tree leading to extant taxa. One might wish for an approach, then, that models such changes - using, for example, a Poisson process - and then locates the changes on the tree. However, we still lack the mathematics to solve for $E(t)$ (e.g. equation 11.19) under such a model (Moore et al. 2016). Given that, we can view current implementations of models where rates vary across clades as an approximation to the likelihood, and one that discounts the possibility of shifts in speciation and/or extinction rates among any clades that did not happen to survive until the present day (Rabosky 2017) - and we are stuck with that until a better alternative is developed!

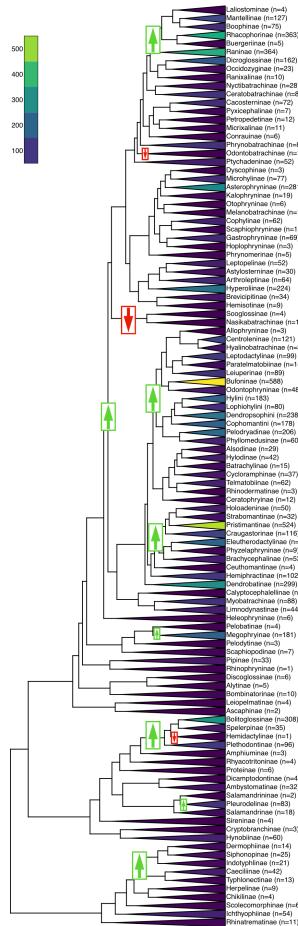

Figure 12.4. Analysis of diversification rate shifts among amphibian clades using MEDUSA (Alfaro et al. 2009). Arrows highlight places where speciation, extinction, or both are inferred to have shifted; green arrows indicate an inferred increase in $r = \lambda - \mu$, while red arrows indicate decreased r .

Section 12.3: Variation in diversification rates through time

In addition to considering rate variation across clades, we might also wonder whether birth and/or death rates have changed through time. For example, perhaps we think our clade is an adaptive radiation that experienced rapid diversification upon arrival to an island archipelago and slowed as this new adaptive zone got filled (Schluter 2000). This hypothesis is an example of density-dependent diversification, where diversification rate depends on the number of lineages that are present (Rabosky 2013). Alternatively, perhaps our clade has been experiencing extinction rates that have changed through time, perhaps peaking during some time period of unfavorable climactic conditions (Benton 2009). This is another hypothesis that predicts variation in diversification (speciation and extinction) rates through time.

We can fit time-dependent diversification models using likelihood equations that allow arbitrary variation in speciation and/or extinction rates, either as a function of time or depending on the number of other lineages in the clade. To figure out the likelihood we can first make a simplifying assumption: though diversification rates might change, they are constant across all lineages at any particular time point. In particular, this means that speciation (and/or extinction) rates slow down (or speed up) in exactly the same way across all lineages in an evolving clade. This is again the Equal-Rates Markov (ERM) model for tree growth described in the previous chapter.

Our assumption about equal rates across lineages at any time means that we can consider time-slices through the tree rather than individual branches, i.e. we can get all the information that we need to fit these models from lineage through time plots.

The most general way to fit time-varying birth-death models to phylogenetic trees is described in Morlon et al. (2011). Consider the case where both speciation and extinction rates vary as a function of time, $\lambda(t)$ and $\mu(t)$. Morlon et al. (2011) derive the likelihood for such a model as:

(eq. 12.1)

$$L(t_1, t_2, \dots, t_{n-1}) = (n+1)! \frac{f^n \sum_{i=1}^{n-1} \lambda(t_i) \Psi(s_{i,1}, t_i) \Psi(s_{i,2}, t_i)}{\lambda[1 - E(t_1)]^2}$$

Where: (eq. 12.2)

and:

(eq. 12.3)

$$\Psi(s, t) = e^{\int_s^t [\lambda(u) - \mu(u)] du} \left[1 + \frac{\int_s^t e^{\int_0^\tau [\lambda(\sigma) - \mu(\sigma)] d\sigma} \lambda(\tau) d\tau}{\frac{1}{f} + \int_0^s e^{\int_0^\tau [\lambda(\sigma) - \mu(\sigma)] d\sigma} \lambda(\tau) d\tau} \right]^{-2}$$

Following chapter 11, n is the number of tips in the tree, and divergence times t_1, t_2, \dots, t_{n-1} are defined measured from the present (e.g. decreasing towards the present day). $\lambda(t)$ and $\mu(t)$ are speciation and extinction rates expressed as an arbitrary function of time, f is the sampling fraction (under a uniform sampling model). For a node starting at time t_i , $s_{i,1}$ and $s_{i,2}$ are the times when the two daughter lineages encounter a speciation event in the reconstructed tree. $E(t)$, as before, is the probability that a lineage alive at time t leaves no descendants in the sample. Finally, $\Psi(s, t)$ is the probability that a lineage alive at time s leaves exactly one descent at time $t < s$ in the reconstructed tree. These equations look complex, and they are - but basically involve integrating the speciation and extinction functions (and their difference) along the branches of the phylogenetic tree.

Note that my equations here differ from the originals in Morlon et al. (2011) in two ways. First, Morlon et al. (2011) assumed that we have information about the stem lineage and, thus, used an index on t_i that goes up to n instead of $n - 1$ and a different denominator conditioning on survival of the descendants of the single stem lineage (Morlon et al. 2011). Second, I also multiply by the total number of topological arrangements of n taxa, $(n+1)!$.

If one substitutes constants for speciation and extinction ($\lambda(t) = \lambda_c$, $\mu(t) = \mu_c$) in equation 12.1, then one obtains equation 11.24; if one additionally considers the case of complete sampling and substitutes

$f = 1$ then we obtain equation 11.18. This provides a single unified framework for time-varying phylogenetic trees with uniform incomplete sampling (see also Höhna 2014 for independent but equivalent derivations that also extend to the case of representative sampling).

Equation 12.1 requires that we define speciation rate as a function of time. Two types of time-varying models are currently common in the comparative literature: linear and exponential. If speciation rates change linearly through time (see Rabosky and Lovette 2008 for an early version of this model):

(eq. 12.4)

$$\lambda(t) = \lambda_0 + \alpha_\lambda t$$

Where λ_0 is the initial speciation rate at the present and alpha the slope of speciation rate change as we go back through time. α_λ must be chosen so that speciation rates do not become negative as we move back through the tree: $\alpha_\lambda > -\lambda_0/t_1$. Note that the interpretation of α_λ is a bit strange since we measure time backwards: a positive α_λ , for example, would mean that speciation rates have declined from the past to the present. Other time-dependent models published earlier [e.g. Rabosky and Lovette (2008), which considered a linearly declining pure-birth model] do not have this property.

We could also consider a linear change in extinction through time:

(eq. 12.5)

$$\mu(t) = \mu_0 + \alpha_\mu t$$

Again, α_μ is the change in extinction rate through time, and must be interpreted in the same “backwards” way as α_λ . Again, we must restrict our parameter to avoid a negative rate: $\alpha_\mu > -\mu_0/t_1$

One can then substitute either of these formulas into equation 12.1 to calculate the likelihood of a model where speciation rate declines through time. Many implementations of this approach use numerical approximations rather than analytic solutions (see, e.g., Morlon et al. 2011; Etienne et al. 2012).

Another common model has speciation and/or extinction rates changing exponentially through time:

(eq. 12.6)

$$\lambda(t) = \lambda_0 e^{\beta_\lambda t}$$

and/or

(eq. 12.7)

$$\mu(t) = \mu_0 e^{\beta_\mu t}$$

We can again calculate likelihoods for this model numerically (Morlon et al. 2011, Etienne et al. (2012)).

As an example, we can test models of time-varying diversification rates across part of the amphibian tree of life from Jetz and Pyron (2018). I will focus on one section of the salamanders, the lungless salamanders (Plethodontidae, comprised of the clade that spans Bolitoglossinae, Spelerpiniae, Hemidactylinae, and Plethodontinae). This interesting clade was already identified above as including both an increase in diversification rates (at the base of the clade) and a decrease (on the branch leading to Hemidactylinae; Figure 12.4). The tree I am using may be missing a few species; this section of the tree includes 440 species in Jetz and Pyron (2018) but 471 species are listed on Amphibiaweb as of May 2018. Thus, I will assume random sampling with $f = 440/471 = 0.934$.

Comparing the fit of a set of models, we obtain the following results:

Model	Number of params.	Param. estimates	lnL	AIC
CRPB	1	$\lambda = 0.05111267$	497.8	-993.6
CRBD	2	$\lambda = 0.05111267$	497.8	-991.6
SP-L	3	$\mu = 0$ $\lambda_0 = 0.035$ $\alpha_\lambda = 0.0011$	513.0	-1019.9
SP-E	3	$\mu = 0$ $\lambda_0 = 0.040$ $\beta_\lambda = 0.016$	510.7	-1015.4
EX-L	3	$\mu = 0$ $\lambda = 0.053$ $\alpha_\mu = 0.000036$	497.8	-989.6

Model	Number of params.	Param. estimates	lnL	AIC
EX-E	3	$\lambda = 0.069$ $\mu_0 = 61.9$ $\beta_\mu = -111.0$	510.6	-1015.3

Models are abbreviated as: CRPB = Constant rate pure birth; CRBD = Constant rate birth-death; SP-L = Linear change in speciation; SP-E = Exponential change in speciation; EX-L = Linear change in extinction; EX-E = Exponential change in extinction.

The model with the lowest AIC score has a linear decline in speciation rates, and moderate support compared to all other models. From this, we support the inference that diversification rates among these salamanders has slowed through time. Of course, there are other models I could have tried, such as models where both speciation and extinction rates are changing through time, or models where there are many more extant species of salamanders than currently recognized. The conclusion we make is only as good as the set of models being considered, and one should carefully consider any plausible models that are not in the candidate set.

Section 12.4: Diversity-dependent models

Time-dependent models in the previous section are often used as a proxy to capture processes like key innovations or adaptive radiations (Rabosky 2014). Many of these theories suggest that diversification rates should depend on the number of species alive in a certain time or place, rather than time (Phillimore and Price 2008; Etienne and Haegeman 2012; Etienne et al. 2012; Rabosky 2013; Moen and Morlon 2014). Therefore, we might want to define speciation rate in a truly diversity dependent manner rather than using time as a proxy:

(eq. 12.8)

$$\lambda(t) = \lambda_0 \left(1 - \frac{N_t}{K}\right)$$

Since speciation rate now depends on number of lineages rather than

time, we can't plug this expression into our general formula (Morlon et al. 2011). Instead, we can use the approach outlined by Etienne et al. (2012) and Etienne et al. (2016). This approach focuses on numerical solutions to differential equations moving forward through time in the tree. The overall idea of the approach is similar to Morlon, but details differ; likelihoods from Etienne et al. (2012) should be directly comparable to all the likelihoods presented in this book provided that the conditioning is the same and they are multiplied by the total number of topological arrangements ($n + 1$)! to get a likelihood for the tree rather than for the branching times. Etienne's approach can also deal with incomplete sampling under a uniform sampling model.

As an example, we can fit a basic model of diversity-dependent speciation to our phylogenetic tree of lungless salamanders introduced above. Doing so, we find a ML estimate of $\lambda_0 = 0.099$, $\mu = 0$, and $K = 979.9$, with a log-likelihood of 537.3 and an AIC of -1068.7. This is a substantial improvement over any of the time-varying models considered above, and evidence for diversity dependence among lungless salamanders.

Both density- and time-dependent approaches have become very popular, as time-dependent diversification models are consistent with many ecological models of how multi-species clades might evolve through time. For example, adaptive radiation models based on ecological opportunity predict that, as niches are filled and ecological opportunity “used up,” then we should see a declining rate of diversification through time (Etienne and Haegeman 2012; Rabosky and Hurlbert 2015). By contrast, some models predict that species create new opportunities for other species, and thus predict accelerating diversification through time (Emerson and Kolm 2005). These are reasonable hypotheses, but there is a statistical challenge: in each case, there is at least one conceptually different model that predicts the exact same pattern. In the case of decelerating diversification, the predicted pattern of a lineage-through-time plot that bends down towards the present day can also come from a model where lineages accumulate at a constant rate, but then are not fully sampled at the present day (Pybus and Harvey 2000). In other words, if we are missing some living species from our phylogenetic tree and we don't account for that, then we would mistake a constant-rates birth death model for a signal of slowing diversification through time. Of course, methods that we have discussed can account

for this. Some methods can even account for the fact that the missing taxa might be non-random, as missing taxa tend to be either rare or poorly differentiated from their sister lineages (e.g. often younger than expected by chance; Cusimano and Renner 2010; Brock et al. 2011). However, the actual number of species in a clade is always quite uncertain and, in every case, must be known for the method to work. So, an alternative explanation that is often viable is that we are missing species in our tree, and we don't know how many there are. Additionally, since much of the signal for these methods comes from the most recent branching events in the tree, some "missing" nodes may simply be too shallow for taxonomists to call these things "species." In other words, our inferences of diversity dependence from phylogenetic trees are strongly dependent on our understanding of how we have sampled the relevant taxa.

Likewise, a pattern of accelerating differentiation mimics the pattern caused by extinction. A phylogenetic tree with high but constant rates of speciation and extinction is nearly impossible to distinguish from a tree with no extinction and speciation rates that accelerate through time.

Both of the above caveats are certainly worth considering when interpreting the results of tests of diversification from phylogenetic data. In many cases, adding fossil information will allow investigators to reliably distinguish between the stated alternatives, although methods that tie fossils and trees together are still relatively poorly developed (but see Slater and Harmon 2013). And many current methods will give ambiguous results when multiple models provide equivalent explanations for the data - as we would hope!

Section 12.5: Protracted speciation

In all of the diversification models that we have considered so far, speciation happens instantly; one moment we have a single species, and then immediately two. But this is not biologically plausible. Speciation takes time, as evidenced by the increasing numbers of partially distinct populations that biologists have identified in the natural world (Coyne and Orr 2004; De Queiroz 2005). Furthermore, the fact that

speciation takes time can have a profound impact on the shapes of phylogenetic trees (Losos and Adler 1995). Because of this, it is worth considering diversification models that explicitly account for the fact that the process of speciation has a beginning and an end.

The most successful models to tackle this question have been models of protracted speciation (Rosindell et al. 2010; Etienne and Rosindell 2012; Lambert et al. 2015). One way to set up such a model is to state that speciation begins by the formation of an incipient species at some rate λ_1 . This represents a “partial” species; one can imagine, for example, that this is a population that has split off from the main range of the species, but has not yet evolved full reproductive isolation. The incipient species only becomes a “full” species if it completes speciation, which occurs at a rate λ_2 . This represents the time it takes for an incipient species to evolve full reproductive isolation (Figure 12.5).

Because speciation takes time, the main impact of this model is that we predict fewer very young species in our tree – that is, the nodes closest to the tips of the tree are not as young as they would be compared to pure-birth or birth-death models without protracted speciation (Figure 12.6). As a result, protracted speciation models produce lineage through time plots that can mimic the properties often attributed to diversity-dependence, even without any interactions among lineages (Etienne and Rosindell 2012)!

Likelihood approaches are available for this model of protracted speciation. Again, the likelihood must be calculated using numerical methods (Lambert et al. 2015). Fitting this model to the salamander tree, we obtain a maximum log-likelihood of 513.8 with parameter values $\lambda_1 = 0.059$, $\lambda_2 = 0.44$, and $\mu = 0.0$. This corresponds to an AIC score of -1021.6; this model fits about as well as the best of the time-varying models but not as well as the diversity dependent model considered above. Again, though, I am not including plausible combinations of models, such as protracted speciation that varies through time.

So far, models of protracted speciation remain mostly in the realm of ecological neutral theory, and are just beginning to move into phylogenetics and evolutionary biology (see, e.g., Sukumaran and Lacey Knowles 2017). However, I think models that treat speciation as a process that takes time – rather than something instantaneous – will be

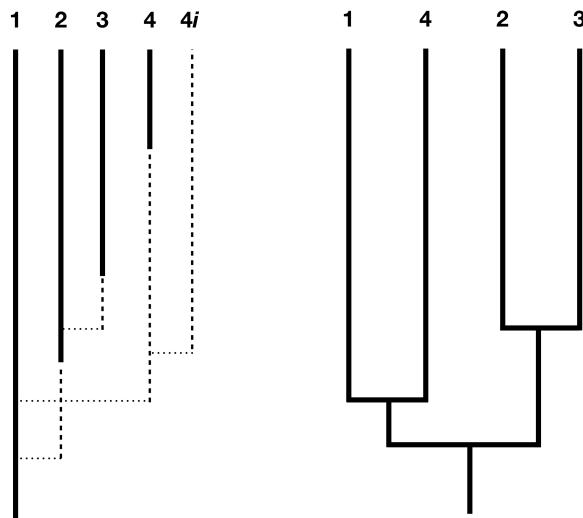

Figure 12.5. An illustration of the protracted model of speciation on a phylogenetic tree. Panel A shows the growing tree including full (solid lines) and incipient species (dotted lines). Incipient species become full after some waiting time, and if that waiting time is not reached before sampling then they are not included in the final species tree (panel B; e.g. lineage 4*i*). Modified from Lambert et al. (2015)

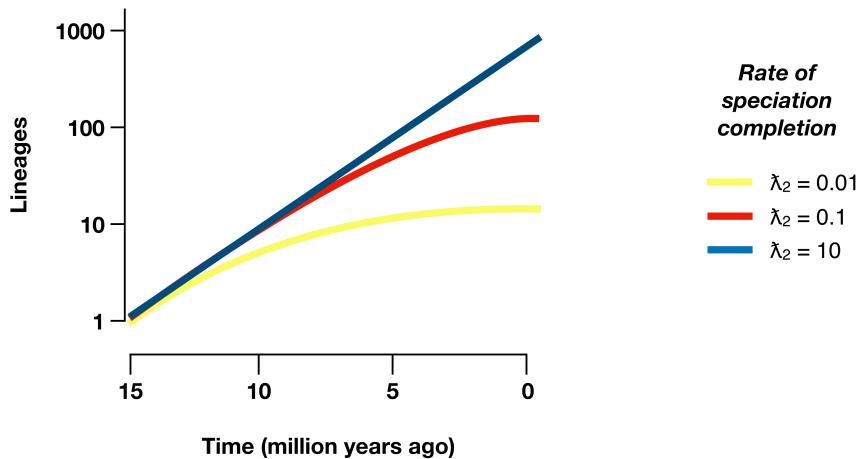

Figure 12.6. Lineage-through-time plots under a protracted birth-death model. Modified from Etienne and Rosindell (2012)

an important addition to our macroevolutionary toolbox in the future.

Section 12.5: Summary

In this chapter I discussed models that go beyond constant rate birth-death models. We can fit models where speciation rate varies across clades or through time (or both). In some cases, very different models predict the same pattern in phylogenetic trees, warranting some caution until direct fossil data can be incorporated. I also described a model of protracted speciation, where speciation takes some time to complete. This latter model is potentially better connected to microevolutionary models of speciation, and could point towards fruitful directions for the field. We know that simple birth-death models do not capture the richness of speciation and extinction across the tree of life, so these models that range beyond birth and death are critical to the growth of comparative methods.

Footnotes

- 1: Even though this approach requires topology, Morlon et al. (2011) show that their likelihood is equivalent to other approaches, such as Nee and Maddison, that rely only on branching times and ignore topology completely. This is because trees with the same set of branching times but different topologies have identical likelihoods under this model.

Chapter 13: Characters and diversification rates

Section 13.1: The evolution of self-incompatibility

Most people have not spent a lot of time thinking about the sex lives of plants. The classic mode of sexual reproduction in angiosperms (flowering plants) involves pollen (the male gametophyte stage of the plant life cycle). Pollen lands on the pistil (the female reproductive structure) and produces a pollen tube. Sperm cells move down the pollen tube, and one sperm cell unites with the egg to form a new zygote in the ovule.

As you might imagine, plants have little control over what pollen grains land on their pistil (although plant species do have some remarkable adaptations to control pollination by animals; see Anders Nilsson 1992). In particular, this “standard” mode of reproduction leaves open the possibility of self-pollination, where pollen from a plant fertilizes eggs from the same plant (Stebbins 1950). Self-fertilization (sometimes called selfing) is a form of asexual reproduction, but one that involves meiosis; as such, there are costs to self-fertilization. The main cost is inbreeding depression, a reduction in offspring fitness associated with recessive deleterious alleles across the genome (Holsinger et al. 1984).

Some species of angiosperms can avoid self-fertilization through self-incompatibility (Bateman 1952). In plants with self-incompatibility, the process by which the sperm meets the egg is interrupted at some stage if pollen grains have a genotype that is the same as the parent (e.g. Schopfer et al. 1999). This prevents selfing – and also prevents sexual reproduction with plants that have the same genotype(s) at loci involved in the process.

Species of angiosperms are about evenly divided between these two states of self-compatibility and self-incompatibility (Igic and Kohn 2006). Furthermore, self-incompatible species are scattered throughout the phylogenetic tree of angiosperms (Igic and Kohn 2006).

The evolution of selfing is a good example of a trait that might have a strong effect on diversification rates by altering speciation, extinction,

or both. One can easily imagine, for example, how incompatibility loci might facilitate the evolution of reproductive isolation among populations, and how lineages with such loci might diversify at a very different tempo than those without (Goldberg et al. 2010).

In this chapter, we will learn about a family of models where traits can affect diversification rates. I will also address some of the controversial aspects of these models and how we can improve these approaches in the future.

Section 13.2: A State-Dependent Model of Diversification

The models that we will consider in this chapter include trait evolution and associated lineage diversification. In the simplest case, we can consider a model where the character has two states, 0 and 1, and diversification rates depend on those states.

We need to model the transitions among these states, which we can do in an identical way to what we did in Chapter 7 using a continuous-time Markov model. We express this model using two rate parameters, a forward rate q_{01} and a backwards rate q_{10} .

We now consider the idea that diversification rates might depend on the character state. We assume that species with character state 0 have a certain speciation rate (λ_0) and extinction rate (μ_0), and that species in 1 have potentially different rates of both speciation (λ_1) and extinction (μ_1). That is, when the character evolves, it affects the rate of speciation and/or extinction of the lineages. Thus, we have a six-parameter model (Maddison et al. 2007). We assume that parent lineages give birth to daughters with the same character state, that is character states do not change at speciation.

It is straightforward to simulate evolution under our state-dependent model of diversification. We proceed in the same way as we did for birth-death models, by drawing waiting times, but these waiting times can be waiting times to the next character state change, speciation, or extinction event. In particular, imagine that there are n lineages present at time t , and that k of these lineages are in state 0 (and $n - k$

are in state 1). The waiting time to the next event will follow an exponential distribution with a rate parameter of:

(eq. 13.1)

$$\rho = k(q_{01} + \lambda_0 + \mu_0) + (n - k)(q_{10} + \lambda_1 + \mu_1)$$

This equation says that the total rate of events is the sum of the events that can happen to lineages with state 0 (state change to 1, speciation, or extinction) and the analogous events that can happen to lineages with state 1. Once we have a waiting time, we can assign an event type depending on probabilities. For example, the probability that the event is a character state change from 0 to 1 is:

(eq. 13.2)

$$p_{q_{01}} = (n \cdot q_{01})/\rho$$

And the probability that the event is the extinction of a lineage with character state 1 is:

(eq. 13.3)

$$p_{\mu_1} = [(n - k) \cdot \mu_1]/\rho$$

And so on for the other four possible events.

Once we have picked an event in this way, we can randomly assign it to one of the lineages in the appropriate state, with each lineage equally likely to be chosen. We then proceed forwards in time until we have a dataset with the desired size or total time depth.

An example simulation is shown in Figure 14.1. As you can see, under these model parameters the impact of character states on diversification is readily apparent. In the next section we will figure out how to extract that information from our data.

Section 13.3: Calculating Likelihoods for State-dependent diversification models

To calculate likelihoods for state-dependent diversification models we use a pruning algorithm with calculations that progress back through

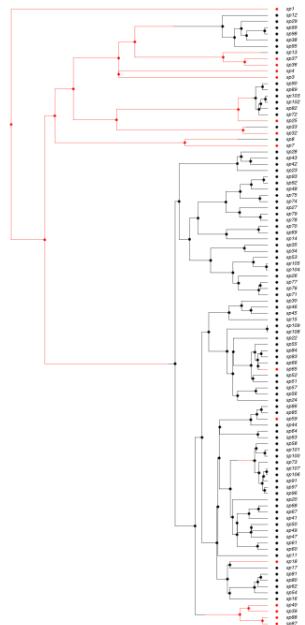

Figure 13.1. Simulation of character-dependent diversification. Data were simulated under a model where diversification rate of state zero (red) is substantially lower than that of state 1 (black; model parameters $q_{01} = 1_{10} = 0.05$, $\lambda_0 = 0.2$, $\lambda_1 = 0.8$, $\mu_0 = \mu_1 = 0.05$).

the tree from the tips to the root. We will follow the description of this algorithm in Maddison et al. (2007). We have already used this approach to derive likelihoods for constant rate birth-death models on trees (Chapter 12), and this derivation is similar.

We consider a phylogenetic tree with data on the character states at the tips. For the purposes of this example, we will assume that the tree is complete and correct – we are not missing any species, and there is no phylogenetic uncertainty. We will come back to these two assumptions later in the chapter.

We need to obtain the probability of obtaining the data given the model (the likelihood). As we have seen before, we will calculate that likelihood going backwards in time using a pruning algorithm (Maddison et al. 2007). The key principle, again, is that if we know the probabilities at some point in time on the tree, we can calculate those probabilities at some time point immediately before. By applying this method successively, we can move back towards the root of the tree. We move backwards along each branch in the tree, merging these calculations at nodes. When we get to the root, we have the probability of the data given the model and the entire tree – that is, we have the likelihood.

The other essential piece is that we have a starting point. When we start at the tips of the tree, we assume that our character states are fixed and known. We use the fact that we know all of the species and their character states at the present day as our starting point, and move backwards from there (Maddison et al. 2007). For example, for a species with character state 0, the likelihood for state 0 is 1, and for state 1 is zero. In other words, at the tips of the tree we can start our calculations with a probability of 1 for the state that matches the tip state, and 0 otherwise.

This discussion also highlights the fact that incorporating uncertainty and/or variation in tip states for these algorithms is not computationally difficult – we just need to start from a different point at the tips. For example, if we are completely unsure about the tip state for a certain taxa, we can begin with likelihoods of 0.5 for starting in state 0 and 0.5 for starting in state 1. However, such calculations are not commonly implemented in comparative methods software.

We now need to consider the change in the likelihood as we step backwards through time in the tree (Maddison et al. 2007). We will consider some very small time interval Δt , and later use differential equations to find out what happens in the limit as this interval goes to zero (Figure 13.2). Since we will eventually take the limit as $\Delta t \rightarrow 0$, we can assume that the time interval is so small that, at most, one event (speciation, extinction, or character change) has happened in that interval, but never more than one. We will calculate the probability of the observed data given that the character is in each state at time t , again measuring time backwards from the present day. In other words, we are considering the probability of the observed data if, at time t , the character state were in state 0 [$p_0(t)$] or state 1 [$p_1(t)$]. For now, we can assume we know these probabilities, and try to calculate updated probabilities at some earlier time $t + \Delta t$: $p_0(t + \Delta t)$ and $p_1(t + \Delta t)$.

To calculate $p_0(t + \Delta t)$ and $p_1(t + \Delta t)$, we consider all of the possible things that could happen in a time interval Δt along a branch in a phylogenetic tree that are compatible with our dataset (Figure 13.2; Maddison et al. 2007). First, nothing at all could have happened; second, our character state could have changed; and third, there could have been a speciation event. This last event might seem incorrect, as we are only considering changes along branches in the tree and not at nodes. If we did not reconstruct any speciation events at some point along a branch, then how could one have taken place? The answer is that a speciation event could have occurred but all taxa descended from that branch have since gone extinct. We must also consider the possibility that either the right or the left lineage went extinct following the speciation event; that is why the speciation event probabilities appear twice in Figure 13.2 (Maddison et al. 2007).

We can write an equation for these updated probabilities. We will consider the probability that the character is in state 0 at time $t + \Delta t$; the equation for state 1 is similar (Maddison et al. 2007).

(eq. 13.4)

$$p_0(t + \Delta t) = (1 - \mu_0)\Delta t \cdot [(1 - q_{01}\Delta t)(1 - \lambda_0\Delta t)p_0(t) + q_{01}\Delta t(1 - \lambda_0\Delta t)p_1(t) + 2 \cdot (1 - q_{01}\Delta t)\lambda_0\Delta t \cdot E_0(t)p_0(t)]$$

We can multiply through and simplify. We will also drop any terms

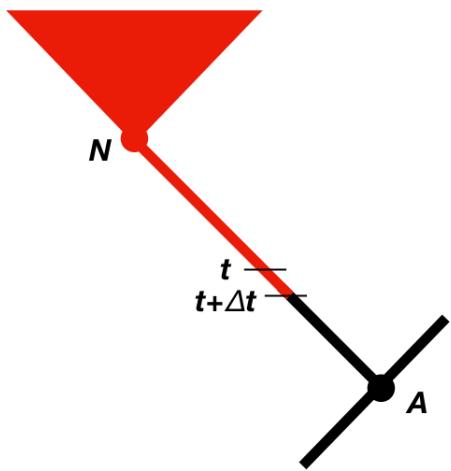

Figure 13.2. Illustration of calculations of probabilities of part of the data descended from node N (red) moving along a branch in the tree. Starting with values for the probability at time t , we calculate the probability at time $t + \Delta t$, moving towards the root of the tree. From Maddison et al. (2007).

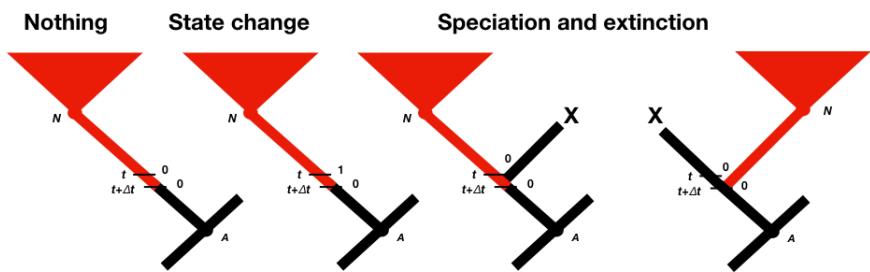

Figure 13.3. The four scenarios under which a lineage with state 0 at time $t + \Delta t$ can yield the data descended from node N. From Maddison et al. (2007).

that include $[\Delta t]^2$, which become vanishingly small as Δt decreases. Doing that, we obtain (Maddison et al. 2007):

(eq. 13.5)

$$p_0(t+\Delta t) = [1 - (\lambda_0 + \mu_0 + q_{01})\Delta t]p_0(t) + (q_{01}\Delta t)p_1(t) + 2(\lambda_0\Delta t)E_0(t)p_0(t)$$

Similarly,

(eq. 13.6)

$$p_1(t+\Delta t) = [1 - (\lambda_1 + \mu_1 + q_{10})\Delta t]p_1(t) + (q_{10}\Delta t)p_0(t) + 2(\lambda_1\Delta t)E_1(t)p_1(t)$$

We can then find the instantaneous rate of change for these two equations by solving for $p_1(t + \Delta t)/[\Delta t]$, then taking the limit as $\Delta t \rightarrow 0$. This gives (Maddison et al. 2007):

(eq. 13.7)

$$\frac{dp_0}{dt} = -(\lambda_0 + \mu_0 + q_{01})p_0(t) + q_{01}p_1(t) + 2\lambda_0 E_0(t)p_0(t)$$

and:

(eq. 13.8)

$$\frac{dp_1}{dt} = -(\lambda_1 + \mu_1 + q_{10})p_1(t) + q_{10}p_0(t) + 2\lambda_1 E_1(t)p_1(t)$$

We also need to consider $E_0(t)$ and $E_1(t)$. These represent the probability that a lineage with state 0 or 1, respectively, and alive at time t will go extinct before the present day. Neglecting the derivation of these formulas, which can be found in Maddison et al. (2007) and is closely related to similar terms in Chapters 11 and 12, we have:

(eq. 13.9)

$$\frac{dE_0}{dt} = \mu_0 - (\lambda_0 + \mu_0 + q_{01})E_0(t) + q_{01}E_1(t) + \lambda_0[E_0(t)]^2$$

and:

(eq. 13.10)

$$\frac{dE_1}{dt} = \mu_1 - (\lambda_1 + \mu_1 + q_{10})E_1(t) + q_{10}E_0(t) + \lambda_1[E_1(t)]^2$$

Along a single branch in a tree, we can sum together many such small time intervals. But what happens when we get to a node? Well, if we consider the time interval that contains the node, then we already know what happened – a speciation event. We also know that the two daughters immediately after the speciation event were identical in their traits (this is an assumption of the model). So we can calculate the likelihood for their ancestor for each state as the product of the likelihoods of the two daughter branches coming into that node and the speciation rate (Maddison et al. 2007). In this way, we merge our likelihood calculations along each branch when we get to nodes in the tree.

When we get to the root of the tree, we are almost done – but not quite! We have partial likelihood calculations for each character state – so we know, for example, the likelihood of the data if we had started with a root state of 0, and also if we had started at 1. To merge these we need to use probabilities of each character state at the root of the tree (Maddison et al. 2007). For example, if we do not know the root state from any outside information, we might consider root probabilities for each state to be equal, 0.5 for state 0 and 0.5 for state 1. We then multiply the likelihood associated with each state with the root probability for that state. Finally, we add these likelihoods together to obtain the full likelihood of the data given the model.

The question of which root probabilities to use for this calculation has been discussed in the literature, and does matter in some applications. Aside from equal probabilities of each state, other options include using outside information to inform prior probabilities on each state (e.g. Hagey et al. 2017), finding the calculated equilibrium frequency of each state under the model (Maddison et al. 2007), or weighting each root state by its likelihood of generating the data, effectively treating the root as a nuisance parameter (FitzJohn et al. 2009).

I have described the situation where we have two character states, but this method generalizes well to multi-state characters (the MuSSE

method; FitzJohn 2012). We can describe the evolution of the character in the same way as described for multi-state discrete characters in chapter 9. We then can assign unique diversification rate parameters to each of the k character states: $\lambda_0, \lambda_1, \dots, \lambda_k$ and $\mu_0, \mu_1, \dots, \mu_k$ (FitzJohn 2012). It is worth keeping in mind, though, that it is not too hard to construct a model where parameters are not identifiable and model fitting and estimation become very difficult.

Section 13.4: ML and Bayesian Tests for State-Dependent Diversification

Now that we can calculate the likelihood for state-dependent diversification models, formulating ML and Bayesian tests follows the same pattern we have encountered before. For ML, some comparisons are nested and so you can use likelihood ratio tests. For example, we can compare the full BiSSe model (Maddison et al. 2007), with parameters $q_{01}, q_{10}, \lambda_0, \lambda_1, \mu_0, \mu_1$ with a restricted model with parameters $q_{01}, q_{10}, \lambda_{all}, \mu_{all}$. Since the restricted model is a special case of the full model where $\lambda_0 = \lambda_1 = \lambda_{all}$ and $\mu_0 = \mu_1 = \mu_{all}$, we can compare the two using a likelihood ratio test, as described earlier in the book. Alternatively, we can compare a series of BiSSe-type models by comparing their AIC_c scores.

For example, I will apply this approach to the example of self-incompatibility. I will use data from Goldberg and Igic (2012), who provide a phylogenetic tree and data for 356 species of Solanaceae. All species were classified as having any form of self incompatibility, even if the state is variable among populations. The data, along with a stochastic character map of state changes, are shown in Figure 13.4.

Applying the BiSSe models to these data and assuming that $q_{01} \neq q_{10}$, we obtain the following results:

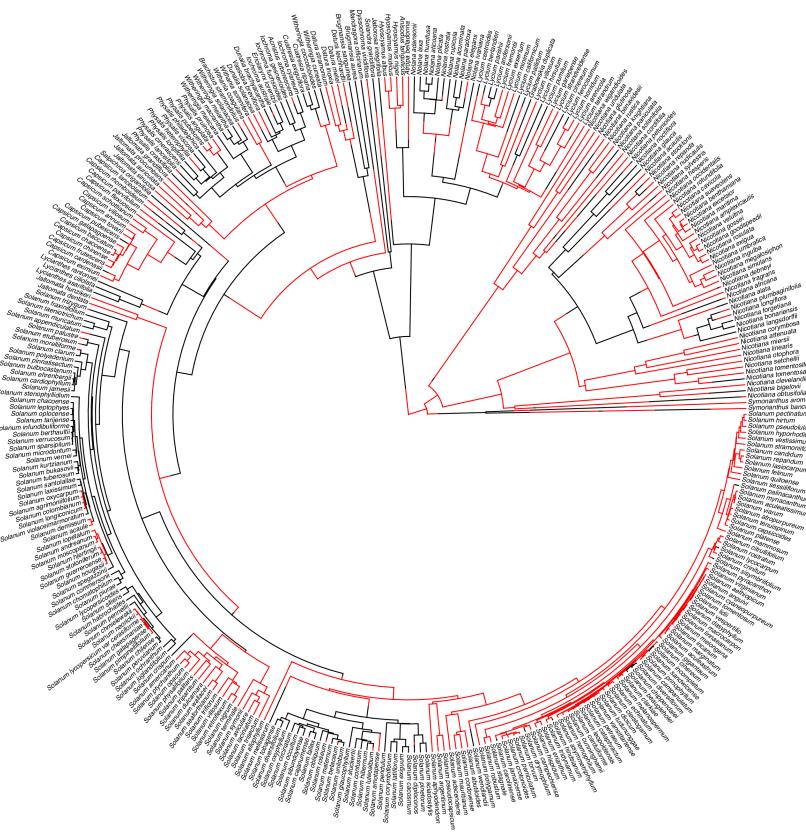

Figure 13.4. Data from Goldberg and Igic (2012) showing presence (red) and absence (black) of self-incompatibility among Solanaceae. Branches colored using stochastic character mapping under a model with distinct forwards and backwards rates; these reconstructions are biased if characters affect diversification rates.

Model	Number of parameters	Parameter estimates	lnL	AIC
Character-independent model	4	$\lambda = 0.65,$ $\mu = 0.57$	-945.96	1899.9
Speciation rate depends on character	5	$q_{01} = 0.16,$ $q_{10} = 0.09$ $\mu = 0.57$	-945.57	1901.1
Extinction rate depends on character	5	$\lambda_0 = 0.69,$ $\lambda_1 = 0.63$ $q_{01} = 0.17,$ $q_{10} = 0.08$ $\lambda = 0.65$	-943.93	1897.9
Full character-dependent model	6	$\mu_0 = 0.45,$ $\mu_1 = 0.67$ $q_{01} = 0.22,$ $q_{10} = 0.06$ $\lambda_0 = 0.49,$ $\lambda_1 = 0.79$	-941.94	1895.9
		$\mu_0 = 0.20,$ $\mu_1 = 0.84$ $q_{01} = 0.29,$ $q_{10} = 0.05$		

From this, we conclude that models where the character influences diversification fit best, with the full model receiving the most support. We can't discount the possibility that the character only influences extinction and not speciation, since that model is within 2 AIC units of the best model.

Alternatively, we can carry out a Bayesian test for state-dependent diversification. Like other models in the book, this requires setting up an MCMC algorithm that generates posterior distributions for our model parameters (FitzJohn 2012). In this case:

1. Sample a set of starting parameter values, $q_{01}, q_{10}, \lambda_0, \lambda_1, \mu_0, \mu_1$, from their prior distributions. For example, one could set prior distribution for all parameters as exponential with a mean and variance of λ_{prior_i} (note that, as usual, the choice for this parameter should depend on the units of tree branch lengths you are using). We then select starting values for all parameters from the prior.
2. Given the current parameter values, select new proposed parameter values using the proposal density $Q(p'|p)$. For all parameter values, we can use a uniform proposal density with width w_p , so that $Q(p'|p) \sim U(p - w_p/2, p + w_p/2)$. We can either choose all parameter values simultaneously, or one at a time (the latter is typically more effective).
3. Calculate three ratios:
 - a. The prior odds ratio. This is the ratio of the probability of drawing the parameter values p and p' from the prior. Since we have exponential priors for all parameters, we can calculate this ratio as (eq. 13.11):

$$R_{prior} = \frac{\lambda_{prior_i} e^{-\lambda_{prior_i} p'}}{\lambda_{prior_i} e^{-\lambda_{prior_i} p}} = e^{\lambda_{prior_i} (p - p')}$$
 - b. The proposal density ratio. This is the ratio of probability of proposals going from p to p' and the reverse. We have already declared a symmetrical proposal density, so that $Q(p'|p) = Q(p|p')$ and $R_{proposal} = 1$.
 - c. The likelihood ratio. This is the ratio of probabilities of the data given the two different parameter values. We can calculate these probabilities from the approach described in the previous section.
4. Find R_{accept} as the product of the prior odds, proposal density ratio, and the likelihood ratio. In this case, the proposal density ratio is 1, so (eq. 13.12):

$$R_{accept} = R_{prior} \cdot R_{likelihood}$$

5. Draw a random number u from a uniform distribution between 0 and 1. If $u < R_{accept}$, accept the proposed value of the parameter(s); otherwise reject, and retain the current value of the two parameters.
6. Repeat steps 2-5 a large number of times.

Applying this method to the self-incompatibility data, we find that again estimates of speciation and extinction differ substantially among the two character states (Figure 13.5). Since the posterior distributions for extinction do not overlap, we again infer that the character likely influences that model parameter; speciation results are again suggestive but not as conclusive as those for extinction.

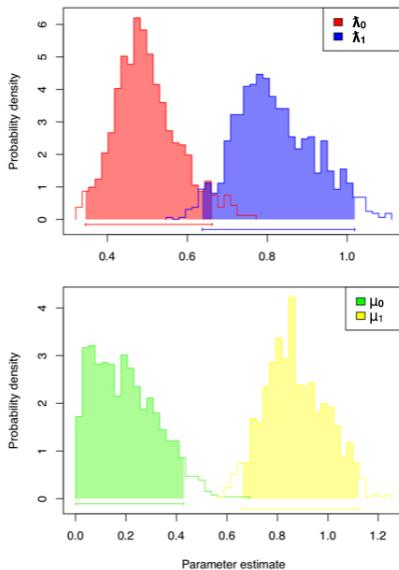

Figure 13.5. Bayesian BiSSe analysis of self-incompatibility. Posterior distributions for character-dependent speciation (λ_0 and λ_1) and extinction (μ_0 and μ_1).

Section 13.5: Potential Pitfalls and How to Avoid Them

Recently, a few papers have been published that are critical of state-dependent diversification models (Rabosky and Goldberg 2015, Maddison and FitzJohn (2015)). These papers raise substantive critiques that are important to address when applying the methods described in this chapter to empirical data. In this section I will attempt to describe the critiques and their potential remedies.

The most serious limitation of state-dependent models as currently implemented is that they consider only a relatively small set of possible models. In particular, the approach we describe above compares two models: first, a model where birth and death rates are constant and do not depend on the state of the character; and second, a model where birth and death rates depend only on the character state (Maddison et al. 2007). But there is another possibility that might be (in general) more common than either of the models we consider: birth and death rates vary, but in a way that is not dependent on the particular character we have chosen to analyze. I say that this is probably a common pattern because we know that birth and death rates vary tremendously across lineages in the tree of life (Alfaro et al. 2009), and it seems probable to me that many of our hypotheses about which characters might contribute to that variation are, at this point, stabs in the dark.

This issue is a normal one for statistical analyses – after all, there are always other models outside of our set of considered possibilities. However, in this case, the fact that state-dependent diversification models fail to consider the possibility outlined above causes a very particular – and peculiar – problem: if we apply the tests to empirical phylogenetic trees, even with made-up data, we almost always find statistically significant results (Rabosky and Goldberg 2015). For example, Rabosky and Goldberg (2015) found that there is very often a statistically significant “signal” that the number of letters in a species name is significantly associated with speciation rates across a range of empirical datasets. This result might seem ridiculous and puzzling, as there is no way that species name length is associated with diversification processes. However, if we return to our alternative model above, then the

results make sense. Rabosky and Goldberg (2015) simulated character evolution on real phylogenetic trees, and their results do not hold when the trees are simulated along with the characters (this is also why Rabosky and Goldberg’s (2015) results do not represent “type I errors,” *contra* their paper, because the data are not simulated under the null hypothesis). On these real trees, speciation and/or extinction rates have vary across clades. Among the two models that the authors consider, both are wrong; speciation and extinction are independent of the character but not constant through time. Of the two alternatives, the state-dependent model tends to fit better because, from a statistical point of view, it is important for the model to capture some variation in birth and death rates across clades. Even a random character will pick up some of this variation, so that the alternative model tends to fit better than the null – even though, in this case, the character has nothing to do with diversification!

Fortunately, there are a number of ways to deal with this problem. First, one can compare the statistical support for the state-dependent model with the support that one obtains for random data. The random data could be simulated on the tree, or one could permute the tips or draw random data from a multinomial distribution (Rabosky and Goldberg 2015). One can then compare, for example, the distribution of dAICc scores obtained from these permutations to the dAICc for the original data. There are also semi-parametric methods based on permutations that have similar statistical properties (Rabosky and Goldberg 2017). Alternatively, we could explicitly consider the possibility that some unmeasured character is actually the thing that is influencing diversification rates (Beaulieu and O’Meara 2016). This latter approach is the most elegant as we can directly add the model described in this section to our list of candidates (see Beaulieu and O’Meara 2016).

A more general critique of state-dependent models of diversification was raised by Maddison and Fitzjohn (Maddison and FitzJohn 2015). This paper pointed out that statistically significant results for these tests can be driven by an event on a single branch of a tree, and therefore be unreplicated. This is a good criticism that applies equally well to a range of comparative methods. We can deal with this critique, in part, by making sure the events we test are replicated in our data. Together, both of these critiques argue for a stronger set of model

adequacy approaches in comparative methods.

Section 13.6: Summary

Many evolutionary models postulate a link between species characteristics and speciation, extinction, or both. These hypotheses can be tested using state-dependent diversification models, which explicitly consider the possibility that species' characters affect their diversification rates. State-dependent models as currently implemented have some potential problems, but there are methods to deal with these critiques. The overall ability of state-dependent models to explain broad patterns of evolutionary change remains to be determined, but represents a promising avenue for future research.

Chapter 14: What have we learned from the trees?

Section 14.1: The Lorax

In Dr. Seuss's "The Lorax" there is a quote that seems appropriate to begin my final chapter (Seuss 1971).

'Mister,' he said with a sawdusty sneeze,
'I am the Lorax, I speak for the trees.
I speak for the trees, for the trees have no tongues."

Comparative methods have been rushing forward at breakneck speed to "speak for the trees" for more than 20 years now. At the same time, we have gained more information about the shape of the tree of life than any time in the history of the planet. So, what have we learned so far? And what can we learn moving forward? Perhaps most importantly, how can we overcome the perceived and actual limits of comparative approaches, and enable new breakthroughs in our understanding of evolutionary biology?

Section 14.2: What we have learned so far

The great success of comparative methods has been, I think, in testing hypotheses about adaptation. A variety of methods can be applied to test for evolutionary relationships between form and the environment – and, increasingly, organismal function. These methods applied to real data have shed great light onto the myriad ways that species can adapt. This has been a great boon to organismal biology, and comparative methods are now routinely used to analyze and test hypotheses of adaptation across the tree of life. Methods for detecting adaptation using comparative approaches are growing increasingly sophisticated in terms of the types of data that they can handle, including massively multivariate gene expression data, function-valued trait data, and data from genome sequencing. One can only expect this trend to continue.

One thing seems certain after a few decades of comparative analysis:

the tempo of evolution is incredibly variable. Rates of evolution vary both through time and across clades, with the quickest rates of both trait evolution and speciation thousands of times faster than the slowest rates. We can see this variation in analyses from relatively simple tree balance tests to sophisticated Bayesian analyses. So, evolution does not tick along like a clock; instead, rates of evolution depend strongly on lineage, time, and place. The details of these relationships, though, remain to be deciphered.

Comparative methods have played a critical role in our understanding of speciation. Studies using lineage-through-time plots have greatly enhanced our knowledge of diversification rates, and a wide range of results have shown increasing evidence for diversity-dependence in speciation (though this interpretation is not without controversy!). This set of studies provide a nice complement to paleobiological studies of diversification rates using the fossil record.

We can already gain some new biological insights as comparisons among clades start to hint at which factors are responsible for the fact that some species are so much more diverse than others. Perhaps for psychological reasons, most studies have tried to determine explanations for the fastest rates of speciation, as seen in young diverse clades like African cichlids and Andean plants. However, given the high potential for speciation and splitting to accumulate species in a geographic landscape, it might be true that the depauperate clades are really the mysterious parts of the tree of life. Many current research programs are aimed directly at explaining differences in diversity across both narrow and broad phylogenetic scales.

Overall, I think it is easy to see why comparative methods have risen to their current prominence in evolutionary biology. Phylogenetic trees provide a natural way to test evolutionary hypotheses over relatively long time scales without requiring any direct historical information. They have been applied across the tree of life to help scientists understand how species adapt and multiply over long time scales.

Section 14.3: Where can we go next?

As emphasized by Harvey and Pagel (1991), comparative methods have proven to be an essential tool in identifying and describing adaptations. However, the scope of comparative methods has broadened, and now seeks to address broad and long-standing theories of macroevolution. It is in this area that I think comparative methods has promise, but awaits new developments and ideas to really make progress towards the future.

The main challenge, I think, is in identifying and testing broad theories of macroevolution. Too many papers focus on “classic” verbal models of macroevolution – many of which have been defined in contradictory ways over the years and can never really be tested. At the same time, new quantitative theories of macroevolution are lacking.

Let me explore this in a bit more detail using the idea of adaptive radiation and the related concept of ecological opportunity. Perhaps, the theory goes, occasionally lineages enter a new adaptive zone full of niches just waiting to be occupied; the lineage then evolves rapidly to fill those niches. Based on this definition, there are several sets of criteria that one might apply to decide whether or not a particular lineage has experienced such an adaptive radiation. There are a few alternatives that are sometimes contrasted to this pattern, like nonadaptive radiation.

The concept of adaptive radiation has been very fruitful for inspiring creative and interesting work on model clades, but (in my opinion) we have mostly failed in terms of really predicting adaptive radiations and separating the phenomenon from ‘normal’ evolution. For example, most studies identify lineages undergoing adaptive radiation *a priori*. Even when the goal is to identify adaptive radiations, some criteria seem hard to pin down; for example, one can require evidence of adaptation, but surely every lineage on the planet has experienced selection and adapted in at least some way over its history. Likewise, we can require common descent, but there is only one tree of life on Earth (that we know!), so eventually one will find that as well. And authors differ dramatically on whether or not adaptive radiations need to be rapid relative to trait evolution and/or lineage diversification in other

lineages. Finally, although a few studies have been able to characterize the unique features of adaptive radiations compared to their close relatives, comparisons across broader sections of the tree of life have mostly failed. We still do not know for certain if there is anything that links the “classic” adaptive radiations (e.g. anoles, Darwin’s finches, mammals) and distinguishes them from evolution in normal clades.

Comparative methods have cast doubt on another cornerstone of macroevolution, that of punctuated equilibrium. As we have argued, comparative methods have had varying success in tackling each of the parts of PE theory, but we can see little evidence to link them into a cohesive whole. For one thing, there is too much evidence that lineages adapt and evolve along branches of phylogenetic trees, rather than just at speciation. Quantitative tests do tend to find some statistical support for the idea that change depends on both anagenetic rates and speciation, but “pure” punctuated equilibrium is increasingly hard to defend.

As for other major macroevolutionary theories, some have received mixed support (e.g. Dollo’s law, escape-and-radiation, cospeciation, key innovations), while others have hardly been tested in a comparative framework, probably due to a lack of methods (the geographic mosaic theory, holey adaptive landscapes).

Section 14.4: A hint at the future of comparative methods

It is perilous to predict the future progress of science. Nonetheless, I will offer a few suggestions that I think might be productive avenues for future work in comparative methods.

First, I think comparative methods can and should do a better job of integrating diverse data into a coherent framework. For example, despite clear connections, neither fossils nor contemporary data on the tempo and genetics of speciation typically can be integrated with phylogenetic studies of diversification (Rabosky and Matute 2013). Research projects with the same goal, like estimating when and why a lineage undergoes speciation, are better integrated than separate. There are

a few hints about how to proceed: first, speciation models that we fit to both phylogenetic and fossil data must be better connected to the process of speciation; and second, analyses need to consider both paleontological and phylogenetic data simultaneously.

Second, it is absolutely essential to fully deal with uncertainty through entire pipelines of comparative analysis, from tree building to model fitting. The easiest way to do this is through a single integrated Bayesian framework, although using each step's posterior as a prior is nearly as good. Even if one is not a Bayesian, I think it is critical to test how tree uncertainty might affect the results of our comparative analyses.

Third, comparative methods require a more diverse set of models that connect better to biological processes. Current models like Brownian motion and OU have, at best, a weak and many-to-one connection to microevolutionary models. Other models are even more abstract; nothing we can measure about an evolving lineage from one generation to the next, for example, can inform us about the meaning of the lambda parameter from a PGLS analysis. This can be fine statistically, but I think we can do better. The easiest connections to make are between comparative methods and quantitative genetics; in this book I explore only the most basic aspects of this connection. More could, and should, be done. For example, no trait models that I know of deal with differences in abundance and range size among species, even though these vary tremendously among even very close relatives and are almost certain to affect the tempo and mode of trait evolution. Here we can look to other fields like ecology for inspiration.

Section 14.5: Summary

Comparative methods occupy a central place in evolutionary biology. This is because phylogenies provide an accounting of the historical patterns of evolution and, in turn, provide a natural way to measure long-term evolutionary dynamics. The first phase of comparative methods was focused strongly on adaptation. As discussed in this book, we have now branched out into a wide number of new areas, including diversification, community ecology, quantitative genetics, and more. This

expansion has involved new statistical approaches that increase the flexibility of comparative methods and their connection to biological processes. I expect this trend to continue, fueled by the creativity and energy of the next crop of young scientists.
